A better arrangement is to place the wood inside a tin box or canister that is provided with a lid. With a bradawl or nail, punch a hole as vent, and burn. These tins are now lumber in every household, and a few usually find their way into every workshop and amateur's laboratory. Mustard, coffee, cocoa, paints, and innumerable other articles of every-day use, are now sold in such tins, and I apprehend that no one within touch of civilisation would have the slightest difficulty, if occasion required, in collecting a cartload of such discarded tins in a very short space of time. The paths trod by the pioneers of civilisation across the vast prairie lands of America are distinctly marked by the presence of such, and far in the depths of the Australian bush have I seen the camping grounds of carriers and travellers strewn with the rejected empties. For our purpose, those tins that are connected at the side and bottom by welt-seam joints are preferable to those that are soldered.

*The Wood to Use.*—A non-resinous wood is best, and oak is as good as any. It is advisable to have the wood as small as the purpose for which it is required will permit; and a close fire, as that of a kitchener, is better than an open one, as the heat is more intense.

*Culinary Uses.*—Housewives and cooks, who know the value of charcoal for culinary purposes, are also likely to find this useful in connection with the preparations of the kitchen.

## KNOTTING, SPLICING, AND WORKING CORDAGE.

BY LANCELOT L. HASLOPE.

### Hitches and Bends.

Two Half Hitches—Builder's Knot—Double Builder's Knot—Timber Hitch—Killick Hitch—Magnus Hitch—Fisherman's Bend—Rolling Hitch—Topsail Halliard Bend—Racking Hitch—Slippery Hitch—Carrick Bend—Sheet Bends—Blackwall Hitch—Midshipman's Hitch—Marlinespike Hitch—Regulating Lashing—Stationers' Knot.

We now come to a somewhat different class of fastenings, though it is very difficult to discover where knots end and bends and hitches begin; indeed, a tie that, under certain circumstances and made a particular way, is called a "knot," differently constructed, and under dissimilar conditions, is called a "bend" or "hitch," though the result is the same in both cases. As an illustration of what I have been saying, we may take two half hitches (Fig. 25), which, if made in another way round a pole, is called a "Builder's Knot." If my readers will analyse the knots I shall set before them, they will find several other similar instances occurring amongst them. A, Fig. 25, is a single hitch: it is merely a loop formed in a rope. This is readily done by holding the rope in the left hand, and giving it a twist with the right; the loop then forms itself, as it were. When a tightly laid piece of cordage is twisted, these loops are apt to arise of their own accord; they are then called "kinks." They are very objectionable, as the cord is sure to part at the kink when a strain is put on it. It is still worse in the case of wire, which breaks readily when once kinked. Tight, hard cordage should always be well stretched before it is used, to avoid kinking. Two half hitches (Fig. 25) form a very useful knot for a great variety of purposes, as they are very quickly made, and will not slip, no matter what strain is put upon them—indeed, the more they are hauled upon the faster they hold. There is no better or easier way of making a rope fast to a hook. First one hitch is slipped on, and then the other on the top of it, and the rope is fast in less than a couple of seconds. This knot is used by surgeons in reducing a dislocation of the thumb joint. Fig. 26 is the builder's knot, which, as said before, is merely two half hitches, but as it is used in places where it is impossible to pass the hitches over the ends of the timber, it is made by holding one end in the left hand, passing the rope round the pole, under the end, round the pole again, above the first part, and under its own part; from its non-liability to slip laterally this knot is always used to fasten one pole to another in fitting up scaffolding, from which circumstance it has acquired its name. If, instead of making the commencement of the knot as shown in Fig. 26, we pass the end, after it has gone round the pole, two or three times round the other part, as in Fig. 2 (page 65), the remainder of the knot is rather more readily made, as it holds itself taut, and will not slip while the end is put round to complete the fastening.

A "Double Builder's Knot" is made the same way exactly as the builder's knot, but the end goes round again, as before, and underneath its own part. This makes it much stronger. When a builder's knot is made on a rope for the purpose of securing a small line to a stout rope, it is called a "clove hitch."

The "Timber Hitch," Fig. 27, is a rough and ready way of securing a piece of timber or any similar thing, and comes in handy on a great many occasions. It is made by bringing the end of a rope round the timber, then round the standing part, and then, taking two or more turns, round its own part. The pressure of the coils one over the other holds the timber very securely, and the more it is hauled on, the tighter it holds. It can also be cast off very readily.

Fig. 28 is a modification of the timber hitch, called the "Killick Hitch." It is much used to fasten a stone to the end of a rope. After making a timber hitch and hauling it taut, a single hitch is made, and slipped over the end of the stone alongside of it. Some of the best fishing grounds are on rocky coasts where an anchor would not hold; and if it did, there might be considerable risk of losing it altogether, from its jamming in the crevices of a rock. In these places a killick, or large stone, slung as shown in Fig. 28, is used, which holds the boat by its own weight, without any risk of getting fast to the ground.

Fig. 29 is a "Magnus Hitch," a good strong method of securing a rope to a spar, as there is little tendency to slip endways along the spar. In making it, take the end of the rope twice round the spar, in front of the standing part, round the spar again, and then through the last bight.

The "Fisherman's Bend," Fig. 30, consists of two round turns round a spar, and a half hitch round the standing part, and through the turns on the spar, and another half hitch above it, round the standing part. It is used for bending studdingsail halyards to the yard, and, in yachts, for bending on the gaff topsail halliards.

A "Rolling Hitch," Fig. 31, is made by taking three round turns round a spar, and then making two half hitches round the standing part of the rope, and hauling taut.

The "Topsail Halliard Bend," Fig. 32, is another bend, used chiefly on board yachts. It is made by bringing the rope twice round the spar, then bringing it back round the standing part, under all the turns, over two turns, and under the last. This hitch is shown open for the sake of clearness, but in practice we jam the coils close together, and haul them all taut.

Fig. 33 is a "Racking Hitch," for hitching a rope on to the hook of a block. Make two bights in a rope, and turn the bights over from you two or three times, and put the two loops on to the hook. This is sometimes called a "cat's paw."

Fig. 34 is a "Slippery Hitch," the value of which consists in the readiness with which it can be cast off in case of emergency; at the same time, it holds securely while there is a strain on the rope A. If the mainsheet of small boats is made fast at all, which is always a more or less risky thing to do, a slippery hitch should always be used as a start. A sharp pull at the end of the rope lets the sheet go at once.

Fig. 35 is the "Carrick Bend." Lay the end of a rope over the standing part, thus forming a loop; then take the end of another rope, and put it under the bight over the standing part at A, under the end at B, over the rope again at C, under its own part, and over the rope B, and haul taut. The parts A and B form the first loop made. This is generally used for binding hawsers together, to increase their length to warp or tow with. This method of binding ropes together has the great advantage of being readily undone without the aid of a pricker or marlinespike, which would have to be used for many knots, after they had been in the

water. As in the sailor's knot, we have but to grasp the ropes just outside the knot, and push the loops inwards, and the knot comes adrift at once.

Fig. 36 shows the clew of a sail, and the round the back of it, under its own part, and over the clew again. The end is generally stopped to the standing part with rope yarn or other small stuff. The knot thus formed is exactly the same as the weaver's knot, Fig. 10 cated method of bending a rope on to a loop; B is the standing part, and A the end of the rope to be bent on a loop already formed. Pass the end down through the loop, round over its own part, and through the loop,

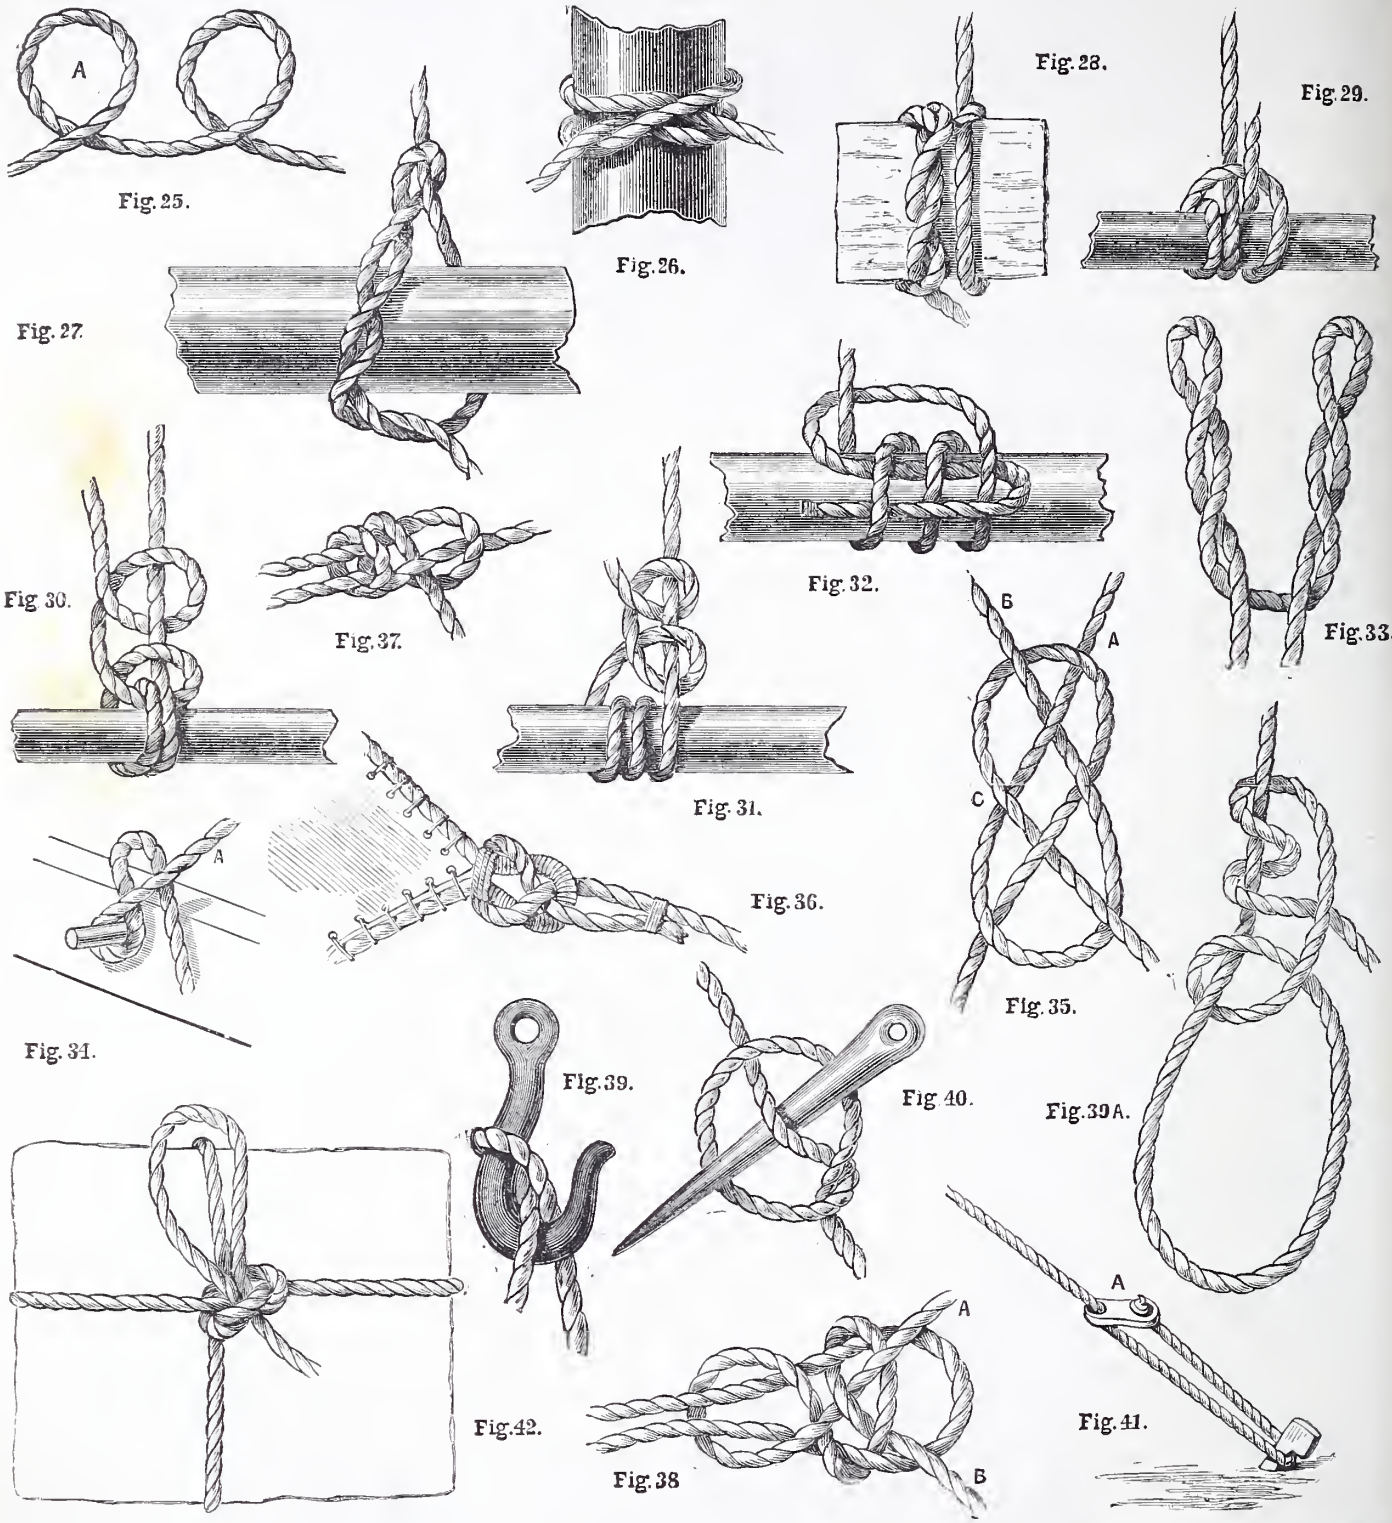

Fig. 25.—Two Half Hitches. Fig. 26.—Builder's Knot and Double Ditto. Fig. 27.—Timber Hitch. Fig. 28.—Killick Hitch. Fig. 29.—Magnus Hitch. Fig. 30.—Fisherman's Bend. Fig. 31.—Rolling Hitch. Fig. 32.—Topsail Halliard Bend. Fig. 33.—Racking Hitch. Fig. 34.—Slippery Hitch. Fig. 35.—Carrick Bend. Figs. 36, 37, 38.—Sheet Bends. Fig. 39.—Blackwall Hitch. Fig. 39 A.—Midshipman's Hitch. Fig. 40.—Marlinespike Hitch. Fig. 41.—Regulating Lashing. Fig. 42.—Stationer's Knot.

method of bending the sheet on to it. This is termed a "Sheet Bend." The sheet is not, as some of my readers might fancy, a part of the sail, but is a rope used in setting a sail, to keep the clew or lower corner of the sail down to its place. In making a sheet bend, the end is passed up through the clew, (page 65). Fig. 37 shows a method of giving additional security to this knot. This is done by passing the end twice round the back of the loop before putting it under its own part. This knot is very much used by fishermen in bending a line on to a loop of gut. Fig. 38 gives another and somewhat more compli- round the back of it, and through its own bight. When hauled taut, this holds more securely than either of the other methods, but, on the other hand, takes longer to make.

The "Blackwall Hitch," Fig. 39, is a ready way of temporarily securing a rope to a

hook. The way of making it is evident from the illustration. As the standing part when hauled upon jams the end against the back of the hook, it holds much more firmly than would be supposed at first sight.

The "Midshipman's Hitch" is an old-fashioned hitch, used for attaching a tail-block to a rope. A round turn is first made over the standing part, and the end is brought up, passed twice round above the first hitch, and then passed out underneath its own part.

The "Marlinespike Hitch," Fig. 40, is used for getting a purchase on the seizing stuff when serving a rope, so as to leave the turns taut. Make a bight in the seizing stuff, and bring it back over the standing part; pass the marlinespike under the standing part, and over the sides of the bight. This is practically identical with the running knot, Fig. 15 (page 137).

Fig. 41 is a "Regulating Lashing," used when the tension of a rope requires altering from time to time. Tent ropes are secured this way, as they require easing in wet weather, and tightening in dry. This is readily effected by slipping the piece of wood A upwards or downwards along the cord, the friction of the cord against the sides of the hole fixing it sufficiently.

The "Stationers' Knot," Fig. 42, is very handy for tieing up a parcel, as it can be made very rapidly, and undone with great ease. Make a running noose at the end of a piece of twine, and bring it to the centre of the parcel; take the twine round the parcel again at right angles, round the noose, and making a bight, slip it under, as shown in the figure. A pull at the end releases the knot instantly, as will be found on making the experiment.

**Fig. 1.—Repairing Worn or Cracked Leather with Patch. Fig. 2.—New Piece of Leather. Fig. 3.—Mode of tucking Patch into Crevice. Fig. 4.—Mode of sewing of Patch.**

## BOOT AND SHOE REPAIRING.

BY WILLIAM GREENFIELD.

### PATCHING.

HOW TO CLOSE IN A PATCH, WITH THE SEAM INSIDE, AND THE WAY TO FASTEN IT DOWN TO THE SOLE.

Now it often happens that when a pair of boots or shoes want soling and heeling (and sometimes before), the uppers want some repairing, such as stitching or patching. I shall, therefore, in this and the following paper give some of the principal methods of repairing such defects, with the way also of fastening such patches as need it down to the sole.

If the boot wants a patch, and does not need soling, it can be fastened down to the sole by sewing, as I shall soon describe; but if the boot has to be soled (and it is not hand-sewn), the sole (or welt, as the underneath sole is termed in machine-sewn) can be prised from the upper as far as the patch is coming to, and the patch tucked under, as the original leather is; and when it is smooth, with no foulness, the under sole can be tacked down with a few small tacks, to secure it till the sole is put on, when a few longer rivets (say, every other one at this part) than those you are using to nail the sole on with will make it as solid as it was at first.

One of the neatest and solidest ways to put in a patch is to close it in. This is done by cutting away the whole of the worn or cracked part of the old leather, as shown at A, Fig. 1. The cut should not have more curve than is possible, for the straighter the cut (that is, from B to C), the easier the piece will be to sew in. In cutting out the piece, be careful not to cut the lining (for by doing so, you put an unnecessary strain on the piece, as then it has no protection from the weight of the body in wear), and at the bottom cut it away right close to the sole. Now take the piece you cut out, and lay it on a piece of new leather of good quality (if the old leather is calf, use calf again, or if it is horse, krup, or porpoise, use calf, but as near the substance as possible; for any other leather it should match, such as kid, patent, etc.), and cut the new piece full large to it, as shown by Fig. 2, of which it will need to be the full size, if it is to be tucked under; but if it is to be sewn down, it will only want to be as large as the dotted line. It will be noticed here that the new piece has not quite so much curve as the old. This is done to give a fulness to the piece equal to what the foot has made in the old leather. The cut from A to B must be even and smooth, and, on the wrong side, holes must be made, as D, D (Fig. 1). This is done by placing it face side down on a board, and about $\frac{1}{16}$th from the edge, make a hole with a closing awl, E (Fig. 1), letting the point come out in the edge of the piece, about four-fifths of the way through, or really as near the face as possible without going through. This you continue the whole way across, putting about fourteen stitches to the inch.

It can now be closed to the boot, first slightly wetting the edge of the old leather. Do not start to sew at quite the end of the new piece, or, when turned over, it will be deficient at the corner. The old leather must not be split, but the awl put right through, and near the edge, so as not to make a hard seam.

For calf or any stout leather, the thread (wax-end) will have to be made with three cords of fine flax, and have bristles on each end. The way to make threads I shall explain in due course. For kid, or any light leather, twist, or stoutish black-thread, will do; a tapered end to either of these is easily made by untwisting them for about an inch and a half, scraping them gently between the thumb and a blunt knife. Then wet or wax them, and twist them back, holding each one separately in the left hand about four inches down, and twist the end on the right knee with the right hand, not too hard, as you may twist off the fine taper that is wanted on to receive the bristle.

In stitching the patch (in fact, all stitching or sewing), each stitch should have the same tension put upon it, being, at the same time, very careful not to pull too hard on the stitch that is to lie on the old leather.

When you have sewn the patch right across, wet the edge again, and scrape off the rough edge, rub it down, and turn the patch down to its right side. Put a last inside, and rub the seam down lightly, but well, on the right side. This can be done with the handle of a table knife, or anything hard and smooth.

Should the vamp be cracked in several places, as E, F, G, and H (Fig. 1), then it will be best to put in a new wing. It can be closed in as described above, from I to J, and blind-stabbed from J to K. In a case like this, it is well to have the top edge a little larger all round, to hide the old holes, and it must be skived a little thinner at this part, about a $\frac{1}{4}$ in. wide, on the wrong side. After you have rubbed this kind of seam down (if it is not a leather that has the grain side out), it will make the seam much neater if it is lightly buffed, or scraped, across from A to B (Fig. 4), and then rubbed down again. In fact, if this sort of patch is put in well, it can scarcely be seen after it has been blacked with blacking.

Previous to sewing the patch down to the sole, the crevice under where the old piece was cut off must be slightly opened with

a chisel, or piece of tapered wood or bone, and the patch tucked in, as shown at A (Fig. 3). This is to enable you, in sewing the patch down, to get the stitches as far back and as much out of sight as possible.

For sewing it to the sole, a sewing awl must be used: it is similar to the closing awl, only a stouter and wider blade.

The thread for ordinary work will need to be about ten cord of No. 9 Patent (price, 2d. per ball), and the awl, although it has to carry the two ends, should only be the substance of one.

The boot will need to be put on the knees, patch side up, and if the piece is on the side shown in either of the above figures, it must lay on the lap, toe from you, as Fig. 3. It must be held very firm on the knees, by means of a strap or stout piece of cord being placed round it, as B (Fig. 3), and passing under the ball of your foot. By this means, it can be held as tight as you please by simply pressing down your toe.

The stitching must be started from A (Fig. 4), the point of the awl being put in on the welt side A, and pushed through to the bottom of the sole, wriggling it a little, that it may find (or make) its own way through at C.

The bristle on the left side is put in first (in all sewing, stitching, or stabbing), and the one on the right side put in underneath it, so that when the stitch is set, it shall be between the thread (on right side) and the patch. This will not only help to lay the stitch back, but, if borne in mind each time, will make the stitches look even and lay flat.

The stitching must, of course, be continued right across to B (Fig. 4), setting about five stitches to the inch, and well tucking the patch under before each stitch is taken.

This done, and the ends cut off, the stitches on the patch side must be rubbed down with the bone, and hammered down lightly with a hammer on the sole side. The surplus of the patch can now be cut off level to the edge of the sole, as shown at C (Fig. 3). The edge can be blacked with ink or blacking, and then rubbed down. A little weak paste on the patch will, if let dry, make it smooth to receive the blacking; and when the whole is blacked and polished, will not only be a neat, but a very solid seam.

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 30.—Smith's Tables and Memoranda for Mechanics, Engineers, etc.

This useful little waistcoat-pocket *vade mecum* for all who are engaged in engineering and the building trades has reached its fifth edition. Its nature and contents may be easily inferred from its title, which, when given in full, runs thus: "Tables, Memoranda, and Calculated Results, for Mechanics, Engineers, Architects, Builders, Surveyors, etc." The matter that it contains was first selected and arranged by Mr. Francis Smith, to meet the daily requirements of men engaged in various mechanical trades some ten years ago; but, in order to keep pace with the advances of science in every direction, the original matter has been carefully revised and enlarged; and a new section has been added, comprising numerous electrical tables, formulæ, etc., which renders the book of special value to electrical engineers. Its price is 1s. 6d., and it is published by Messrs. Crosby Lockwood & Co., 7, Stationers' Hall Court, Ludgate Hill, London, E.C.

### 31.—Hartley & Co.'s "Kristaline" and New Cold Lacquers.

I have much pleasure in calling the attention of metal workers, photographers, and others to whom such specialities may be useful, to the excellent lacquers prepared and supplied by Messrs. J. E. Hartley & Co., Electricians and Electro-Metallurgists, St. Paul's Square, Birmingham. I received samples of these lacquers, and specimens of metals and photographs treated with them, some time ago; but I have purposely withheld my notice until lapse of time should bear its testimony to their endurance, and, therefore, to their commercial value and utility. The samples of lacquers to which I refer were one of a pyroxilin dip lacquer, called "Kristaline," by Messrs. Hartley & Co., and two others of "Improved Hard Cold Lacquers"—a transparent lacquer and a gold-colour lacquer, for application to metals when cold—small articles, when brushed with these preparations, being placed on a stove to dry, but larger things, too large, in fact, to be placed on a stove, being left to dry cold. The specimens sent were: (1) a piece of steel, part lacquered with cold *transparent* lacquer; (2) a piece of brass lacquered, part with cold *gold*, and part with cold *green bronze* lacquer; (3) a piece of brass, silver-plated, then lacquered with Kristaline on one half of it, and afterwards hung over sulphur fumes to show that they have no tarnishing effect on the lacquered part; and (4) a photograph on opal, coated with Kristaline, which protects the gelatine film, and allows of dust or dirt being wiped off with a damp cloth without injury to the photo. In reference to these, I may say that what is said of the photo. is correct in every particular, while the lacquered metals are as bright and untarnished as they were on the day they reached me, though the *unlacquered* portion of the steel shows specks and spots of rust, and that of the brass is dull and clouded.

With regard to the method of applying the lacquers, it is necessary to point out that, although the cold lacquers may be, and I may say should be, applied with the brush, the Kristaline cannot be brushed on work owing to the pyroxilin it contains. Articles to be treated with it must be *dipped* in it; and if the articles be too large to be dipped, the lacquer must be poured or ladled over them, as in this way a small quantity is sufficient for a very large article.

Messrs. Hartley & Co. claim for the pyroxilin lacquer Kristaline: (1) that it is practically indestructible, as neither gases, acid fumes, nor sea air affect it; (2) that it is waterproof; (3) that it is perfectly transparent; and (4) that it is absolutely colourless. For the cold lacquers they claim: (1) that they can be brushed on cold metal, and on the largest articles, with as much facility as on the smallest; (2) that they have more body than ordinary lacquers; (3) that they leave no brush-marks nor treacly appearance; (4) that they can be applied by others than skilled lacquerers; (5) that as there is no loss from evaporation, one gallon goes as far as two gallons applied with heat: and, as skilled lacquerers are unnecessary, they are far more economical than other lacquers; and (6) that they resist atmospheric action longer than other lacquers. Messrs. Hartley & Co. have submitted the names of leading firms by whom Kristaline is used for lacquering silver and gilt ware, gilt and silvered navy buttons, brass foundry and opal photos.; but these, for obvious reasons, I cannot insert, as the names are mentioned for my own information only. The cold lacquers are used generally by brass founders, chandelier makers, engineers, electricians, bicycle and tricycle makers, steel workers, range makers, and for large work, where lacquers applied with heat are wholly inapplicable. I feel sure that Messrs. Hartley's specialities in lacquers will be appreciated by those to whom they are as yet unknown, and who may be led by this notice to become practically acquainted with them—as fully appreciated, indeed, as they seem to be by all who already use them. Messrs. Hartley & Co. will, I am sure, readily forward to any applicant their price list, which will supply all information with reference to prices, and which contains a few remarks on the pyroxilin lacquer, and describes the method of application at greater length than I can do here.

### 32—"Geometric Turning Simplified."

Many readers of WORK are, I am inclined to think, enthusiasts in turning, and especially in the higher branches of the art. To such as these, if they are not already acquainted with it, I venture to recommend a thin octavo volume of sixty-two pages, entitled "Geometric Turning Simplified," written by Mr. W. H. Northcott, C.E., the well-known author of "Lathes and Turning," and published by Messrs. E. & F. N. Spon, 125, Strand, W.C. The price of the book I do not know, but information on this point may be easily obtained by application to the publishers, or to the London Lathe and Tool Company, 37, Pomeroy Street, New Cross, London, S.E., by whom all the apparatus to which reference is made in the volume is made. The object of the writer is to show how geometric and ornamental turning may be practised without the need of the expensive lathes and apparatus hitherto thought necessary; and, in fact, the work described is done by the aid of a simple instrument devised by the author, which permits the operator to practise geometric turning of several sorts in any light lathe, however simple its construction, and in any light milling machine. The work is profusely illustrated with engravings of the apparatus employed, and the patterns that may be produced, each pattern, from those of simple form to others most complex and intricate in appearance, being accompanied by a description of the position of the tool, and the manipulation required in order to produce it.

### 33.—Colours for Marbling Purposes.

The following is taken from "Instructions for the Use of Colours for Marbling Purposes," to produce colours for extra shades and tints, issued for their customers by Messrs. George Royle & Son, Bookbinders' Tool Cutters and Material Dealers, Manufacturers of Marbling Colours, etc., 6, Lovell's Court, Paternoster Row, London, E.C. To produce a single colour from an assortment—yellow and carmine or dark red produce *scarlet* or *vermilion;* carmine and blue, *deep lilac, violet*, and *purple;* carmine, yellow, and black, *rich brown;* yellow and black, *bronze green;* carmine and white, *pinks of any shade;* azure blue, white, and carmine, *deep tones of lilac;* violet and white, *pale lilac* or *lavender;* Chinese blue and white, *pale blue;* Chinese blue, indigo, and yellow orange, *any tone of emerald green;* pale yellow, chrome, and carmine, *amber;* burnt umber and scarlet lake, *red brown;* burnt sienna, shaded with lake, *light brown;* burnt sienna and orange, shaded with white, *salmon*. The following are combinations of colours which harmonise well—scarlet, red, and deep green; light blue and deep red; orange and violet; yellow and blue; black and light green; dark and light blue; carmine and emerald; red, yellow, and blue; orange, black, and light blue; light salmon, dark green, and scarlet; brown, light orange, and purple; dark brown, orange, yellow, and blue; crimson lake, green, yellow, and black; black, green, dark red, and sienna; scarlet, dark green, lavender, and black; azure blue, vermilion, light green, and lilac; sienna, blue, red, and black. In order to give the desired effect for marbling purposes, the finest colours are required. Messrs. Royle & Son supply in 1 lb. tins, at prices ranging from 2s. to 26s. per lb., the following assortment of colours: finest drop carmine lake, second carmine, common lake—light or dark, indigo, yellow, orange, Chinese blue, drop ivory black, indigo black, burnt umber, azure blue, sienna, dark and light green, ultramarine. These will be found quite sufficient for all purposes, the instructions given above being such as will enable any marbler to mix his own shades. THE EDITOR.

## SHOP:

### A Corner for Those who Want to Talk It.

* *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—Letters from Correspondents.

**Instruction Classes.**—Rev. W. Wade (*St. Peter's Vicarage, Fulham, S.W.*) writes:—"Will you allow me to appeal to one or two of your readers who have a few hours' leisure at their disposal in the week? I am most anxious to start industrial classes for the boys of the children's guild connected with this parish. Unfortunately, the ordinary clerical training does not include instruction in any form of mechanical art, and my own fingers can do little else beyond wielding a pen. However, I hope this poor skill will stand me in good stead now if you will allow these lines to appear in your Journal. I should be most grateful if any gentleman, who could devote an hour or two in the week to the instruction of about a dozen boys (by way of a beginning) in one of the minor arts and crafts—such as wood carving, or the bent iron work now so popular—would communicate with me."

**Dry Battery.**—J. A. M. (*London, N.W.*) writes to H. E. (*London, N.W.*):—"In reference to your note in Work (No. 111, page 110) on how to make a dry battery, I have correctly and closely followed your instructions, and found them to be a failure. Thinking perhaps the quantities were not sufficient, I afterwards tried double quantities, and, after letting them stand for three or four days, I did not find the slightest result. If you will kindly furnish me with further instructions on this, or tell me of any other method of how to make a dry battery, through Work, you will oblige."

**Decoration in Applied Art.**—The Secretary of the City and Guilds of London Institute for the Advancement of Technical Education (*Technical College, Finsbury*) writes:—"An important meeting of representative men in the painting trade met recently at the above College, to consider what means could be taken to improve the quality of the workmanship in their trade. The chair was taken by J. D. Crace, Esq. A paper was read by Mr. Wm. Fourniss, Instructor in Decoration in the Applied Art Department of the College. A discussion followed, which resulted in the following resolutions being carried unanimously:—1st, That it is expedient that trade classes for painters should be established for the benefit of the trade. 2nd, That the Guilds of London should be respectfully requested to establish trade classes for painters at the Finsbury Technical College. Some discussion occurred in reference to the question whether or not certificates should be offered and given for proficiency in the painting trade, in which Mr. J. Shaw took part. No resolution, however, was come to in respect to this. Dr. Silvanus P. Thompson, Principal of the College, and J. D. Crace, Esq., chairman of the meeting, gave their entire concurrence with the objects of the meeting."

**Mail-Cart Springs.**—The Victor Cycle Company write:—"Several of your readers have written us, at various times, respecting springs for mail carts. We have now arranged to supply these as well as wheels."

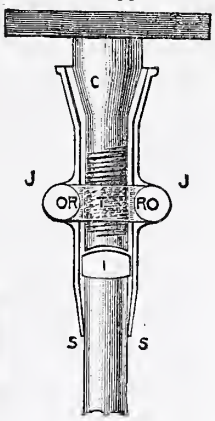
**Small Tin Boxes.**—A. G. (*Sheffield*) writes:—Mr. A. Truelove's address (see No. 112, page 126) is 111, Carver Street, *not* 14, as stated."

**Cold Water on Saws.**—A. R. (*Scorrier*) writes:—"In No. 113 of Work, page 139, W. H. R. (*London, N.W.*) writes in reference to trueing circular saws when buckled. A saw may run wild, as W. H. R. terms it, through undue heating, and by freeing the timber from the saw, and letting it run a little while, even if there is no water thrown on it, the saw being properly packed, it will run true again. A saw may run wild through unfair usage, and consequently become buckled; but if the plate is once buckled, throwing cold water on it will not take out the buckle. I have had to do with saws a number of years, but never threw as much as a pint of water on a saw to get it to run true. When I see men throwing water on a saw to try to get it to do its work, I am quite satisfied that there is something wrong. I know it is an old practice, but men in these days should get beyond such a system of working. In Vols. I. and II. of Work, there are several reasons given why saws run as stated by W. H. R.; and I would advise all readers of Work, who have not the above numbers, to get them. I think the price of each Vol., ready bound, is 7s. 6d."

**Patents.**—A. B. L. (*Newbury*) writes:—"I wish some one of your readers, conversant with the Patent Office, Patent Agents, and Patent Law, would consider the subject of a concise treatise to throw the fullest light upon all appertaining to Patents."

### II.—Questions Answered by Editor and Staff.

**Billiard-Cue Tips.**—T. R. (*Belford*).—The tips of billiard cues are pressed in by a screw working in a socket which holds on to the cue the tighter the screw is applied. I send a rough sketch, useful



Billiard-Cue Tip.

to cue-makers; but most of these workmen have their own devices to ensure a close-down fit of rubber to the wood. The diagram is a sectional elevation sketch. A cross-bandled key or screw-pin with a coned shoulder (C) fits into an expanding double-jawed gripper (J, J), which is formed of two blades of iron or brass slightly segmental, to fit the screw-pin and end of cue. These blades are jointed to a solid ring by lugs hinged to projections from the ring. The middle hole in the ring is threaded to take a screw on the pin (T). The extremities of the blades (S, S) further from the cores grip the cue by the action of the cone shoulder forcing open the opposite ends of the blades, acting as a vice on the cue, holding tighter the more the rubber is pressed down by screwing the pin on to it at I.—J. C. K.

**Flower-Box for Bay Window.**—R. G. (*Streatham Hill*).—A very handsome-looking flower-box may be made for your bay window in the manner I am about to describe, and which I hope you will understand by the rough sketches given. Instead of making your flower-box in one piece as you suggest, and putting the tiles in the front of it, you will do much better to have the tiles in a separate front; it can then be lifted away from the sill when required, or the boxes can be removed for gardening operations if necessary. In Fig. 1 you have a sketch of the arrangement when in position. The front board containing the tiles should be about 2 in. back from the edge of the window-sill, and three boxes made to fit the spaces between it and the front and side windows. Fig. 2 shows a section through the front and the box. To get at the exact

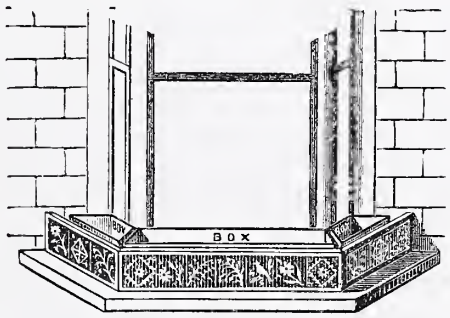


Fig. 1.

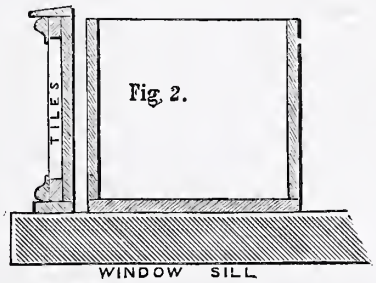

Fig. 2.

Fig. 3.

Flower-Box.

sizes of the wood, you must first purchase your tiles and then make the fittings to suit them; but, for the sake of example, I will suppose that they are 6 in. square: the backboard on which they are laid would thus be 8 in. wide, and would have a batten 1 in. wide, and just the thickness of your tiles, nailed along the top and bottom edges and down the ends of each of the three pieces of the front; the tiles are then laid in their place, and a 1½ in. moulding, of whichever pattern pleases you best, mitred round them. The ends of these front panels are now bevelled to fit each other, and held together by a pair of backfold engines at each joint; these hinges admit of the ends being folded flat to the front when the panelling is removed from its position, as, if rigid, it would be awkward to handle. To steady it when in its place, a hook and eye at each end may be used, the hook being on the inner side, and the eye either in the wall or on the woodwork of the window, whichever answers best. A piece of ⅝ in. wood runs along the bottom of the panelling, and a similar piece on the top, which is bevelled towards the front to throw off the water. Yellow deal should be used both for the front and for the boxes; the moulding you can buy ready for use at almost any timber yard. I think a few minutes' study of Fig. 2 will make the foregoing instructions clear to you, and Fig. 3 will show how the ends are meant to be hinged. The boxes should be made of ¾ in. wood, and may be lined with zinc if preferred; they will, however, last a good many years without lining, and a pipe should be run from near the bottom of each out over the window-sill to carry off the drainage. Another plan is to dispense with boxes altogether. Make your front panels as described, and when in position put your flowers in pots behind them; this is a very good arrangement, as it lessens the labour involved in carpentering, and also admits of changing the plants whenever required, thus enabling you always to have a good show of flowers at your window. A number of minor details and modifications may suggest themselves to you as you proceed with the work, and if you find any difficulty write again. That drawing attached to your letter was of the utmost service in giving me an idea of exactly what you wanted, and I wish all querists would adopt a similar method (where possible) when writing to Work for information; it would so simplify the task of answering, and tend to their getting the requisite replies. I may just add that if you still think of making three boxes, and not using a front as described, the details given for the panelling of the front will equally apply to the panelling of the boxes.—G. le B.

**Electric Belt.**—W. W. J. (*Great Broughton*).—Any size of wire may be used to connect the discs on the belt described on page 827, Vol. II. You may use brass wire uncovered if you cannot get silk-covered copper wire, or you may use uncovered copper wire. Fine wire braid is best, because more flexible than any other. By watching the replies to others in "Shop," you may learn much more about these belts.—G. E. B.

**French Polishing.**—V. S. (*Sheffield*).—By the time this appears in print you will no doubt have noticed that a series of articles on French Polishing has commenced in the present volume of Work—the first in No. 105, the second in No. 108—to be followed by others. These will, I feel certain, suit your purpose better than any book I can recommend. As regards your failures to obtain a level body of polish, perhaps you work your rubber too straight (this will get the work into ridges), instead of circular, as shown on p. 54, No. 108, Vol. III. of Work. A good saying of an old master of mine was, "Keep round the outside edges and well into the corners; the middle will take care of itself." This rule applies well in the case of narrow slips and panels; on a larger surface it will be necessary not to trust too much to the middle taking care of itself. Again, the shape and pliability of the polish rubber have much to do with success. You cannot get into sharp corners and close to the edges of sunk panels, etc., with a round or badly shaped hard rubber. The best shape is one resembling a pear cut in half. It will assist you in keeping the surface level if, when bodying up, you give the work a few slight taps occasionally with a little fine pumice powder tied up in a piece of rag. Use this with caution at first; many amateurs court failure by a too liberal use, thereby breaking up instead of levelling the surface.—Lifeboat.

**Stain for Cabinet.**—J. W. (*Tranmere*).—Fretwork is at all times difficult; it requires tact that can only be got by practice. This difficulty is rendered doubly so by attempting to do it with new rubbers. If you practised first on some flat surfaces, it would place you in possession of rubbers which would save you a lot of trouble, besides giving you such an insight into the *modus operandi* that will enable you to do your cabinet more satisfactorily to yourself. If it is light oak and you wish it simply darkened, this can be best accomplished by shutting it up in an air-tight box or cupboard, on the bottom of which has been placed an open dish of liquid ammonia; or if required darker, or walnut colour, it may be wiped over with a stain made as follows: One pennyworth of nut galls, ½ lb. American potash, 1 pennyworth of vandyke brown; 1 gallon of water; or a little vandyke brown and brown umber, and just a dash of black, made into a thin paste with liquid ammonia, and then thinned down with water till you have the required shade. But do not apply any liquid stain swimmingly; the less they are used on fretwork the better, owing to their tendency to cause it to twist. It is best to use a small sash tool to enable you to get into the interstices, which must not be omitted. Particulars of "How to French Polish" and "The Rubber in French Polishing" have appeared in Nos. 105 and 108, which please read.—Lifeboat.

**Horse-Power.**—F. C. B. (*Lambeth*).—One horse-power is the unit employed for expressing the rate of working a machine, and is equal to 33,000 foot-pounds per minute. This may be explained thus: If I lift a weight of 10 lbs. to a height of 3 ft., I do a certain amount of work; if I lift 20 lbs. through 3 ft., or 10 lbs. through 6 ft., I do twice that amount of

work, and so on. To measure this work, we take the amount of work done in raising 1 lb. to a height of 1 ft. as unit, and call this a "foot-pound." Thus, if I lift 15 lbs. to a height of 4 ft., I do 15 × 4—*i.e.*, 60 —foot-pounds of work; if a carpenter urges his plane forward through 3 ft. with a force of 11 lbs., he does 33 foot-pounds of work: or if a weight of 360 lbs. be raised through a height of 150 ft., the work done is 54,000 foot-pounds. But when we wish to measure the work done by powerful engines, etc., the figures beeome so large as to be confusing, and so another unit is adopted in the same way that a pound is used as the unit for weight, and we say an article weighs so many "pounds"; but when thousands of pounds are to be used, another unit, a ton, is adopted, and we speak of so many "tons." Watt estimated that an average horse eould, in one minute, do an amount of work equivalent to raising 33,000 lbs. through 1 ft., and this amount of work—viz, 33,000 foot-pounds—has been adopted as the unit of work for engines, machines, etc., and is ealled a "horse-power" (H.P.). A 4 H.P. engine, therefore, is one that ean do four times this amount of work, or, in other words, can do 132,000 (*i.e.*, 33,000 × 4) foot-pounds of work per minute. The rate at which a man does work per minute is taken at 3,300 foot-pounds, or one-tenth that of a horse.—F. B. C.

**Electric Belt.**—J. L. D. (*Downham Market*).—In making the belt as advised to G. F. R. (page 827, Vol. II. of WORK), have a metal elasp at the ends, such as that on boys' and cricketers' belts. Solder a fine insulated wire to, say, the left-hand half of the clasp, and to the first disc of copper or of zinc on the belt; if to the eopper, then connect the opposite dise of zinc to the next disc of copper, and so on throughout the belt. This will leave a disc of zine unconnected at the right-hand end of belt; connect this to the other half of the clasp. When the belt is off there will not be any aetion, but when it is fastened around the body by the metal elasp the circuit will be completed through the clasp, and the battery will be in action.—G. E. B.

**Manchester Motor.**—W. J. S. (*Glasgow*).—As you got the eastings for this motor and the instructions for winding it from Mr. Bottone, I think you ought to have made complaint direct to him at first, instead of writing to us. You must have misunderstood Mr. Bottone's instructions altogether. I do not think he eould have ever led you to expect a ¼ horse-power from your motor when worked with current from twelve quart eells. You could not reasonably expect more than ⅓ horse-power from the motor with such small battery power. It ought to move, however, with the current from this number of eells; and I suspect the cause of its failure to lie with your own workmanship. You have either wound it badly and caused the coils to leak, or connected the coils wrongly to the terminals, or got the brushes in a bad position. Try a different angle for the brushes until you get the best effects. Alter the connections. You may try the coils in parallel, but I do not think you will get over the difficulty in this way. Test the winding for insulation, as directed on page 676, Vol. II. of WORK. If you find this imperfect, you will have to unwind the wire, find out the faults, insulate the bare spots afresh, and re-wind the machine. When you have thoroughly overhauled the machine and tested every part, connect up three of your quart eells to the terminals with two short lengths of No. 16 wire: see that all connections are clean. Then move around the rocker until your brushes are at the proper angle, and I will warrant you will get the armature to move, if *you* have properly done your part. I suspect that you ean find somewhere among your instruetions from Mr. Bottone a letter telling you to use a battery of thirty-five quart eells to fully develop ¼ horse-power with the motor he instructed you to make, since it will take quite this number of eells to send 5 ampères of current through the machine; and this will be needed to develop ¼ horse-power after providing for waste in the machine.—G. E. B.

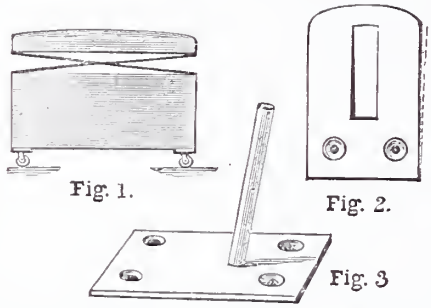
**Photo Frames.**—H. H. (*Basingstoke*).—Frames are sometimes fitted with glass and sometimes not. Those of small size, say up to 8½ in. by 6½ in., are frequently without; larger sizes are usually provided with glass. The only purpose it serves is to lessen the risk of breaking the negatives, which increases with the size of the plate. Stout plate glass is eommonly used.—D.

**Photographing.**—A. S. W. (*No Address*).—Carefully read any elementary handbook on the subject. One by Capt. Abney is very reliable. The chemieals may be purehased at any photographie material dealer's. Chemists and druggists can generally supply all that are required.—D.

**Camera Bellows.**—G. P. (*Elgin*).—The buckram, as sample, will do, but rather thinner would be better, as the paste and Amerieau cloth add considerably to the substanee. Set off the size at eaeh end, and draw lines from the corners at the broad end to those of the narrow end, and fold aeeordingly; if this is properly done the result will be straight. Make a pattern in brown paper by folding a sheet in a conically shaped tube of the right dimensions, and joined at the eorners; you will then at onee see how to shape the material to the best advantage. If the folds are equal the result cannot fail to be right.—D.

**Lantern Slides.**—J. A. (*Leeds*).—The enclosed specimen seems to be all that the introducer claims for it. With regard to non-liability to breakage, there is no doubt it is much less fragile than glass. The specimen sent was, however, broken, with a clear, sharp fraeture; but anything that will stand the test of postage; without protection is of necessity particularly tough. The ordinary exigencies of lantern exhibitions would probably be insuffieient to cause damage. The very thinness would be apt to give rise to diffieultics in passing them through the lantern, unless mounted in some way to add to their substance, but the cardboard mounts may supply this.—D.

**Ottoman Couch Lid.**—J. (*Portsmouth*).—*Re* the hanging of eouch lid, so that it opens either way. It might easily be effected by webbing it on the underside of the lid in the same manner that a elothes-horse is webbed. Of course, a better class of webbing should be used: about the same as is used on Butler's tray stands. It should be tacked firmly on the edge of the box, and then earried aeross the box to the other edge, and tacked firmly to the underside of the lid; now taek another piece on the opposite edge of the box (and in sueh a position that it will come close to the side of the first piece), and carry it across the box to the underside of lid; the other end of the lid must be done the same, and if done properly the box will open from either side. Of eourse, the webbing must be strong, and firmly fastened to box and lid with at least ¾ in. tacks, put in neatly, so as not to split or be unsightly. Perhaps Fig. 1 will explain itself. Another way would be to get four brass plates made with slots in them, and four plates with pins fixed in them: these should take the form of Figs. 2 and 3. Supposing the box



Ottoman Couch Lid. Fig. 1.—End of Ottoman Couch with Lid raised (out of Position), to show Method of attaching Webbing. Fig. 2.—Brass Plate. Fig. 3.—Plate and Pin.

to be made of ⅜ in. stuff, the illustrations are full size. The plates (Fig. 2) should be screwed down to the edge of the box, allowing the slot to project to the inside, about 3 in. from eaeh end; the pins (Fig. 3) on the lid should be screwed down in such a position that the lid will eome level all round. The best way to get the right place to put them would be to place a tack, point upward, on the slot plates, exactly where we want the pin to come, and then placing the lid on earefully. A little pressure will cause the taeks to stick, and we shall know where to put the plates; however careful we may be, we may expect to have to move them before we get them exactly right; for this reason, only one screw should be put in each plate, till we are sure the plates are in the right position. If a tape is securely fixed to keep the lid from going right back (in tho centre), it will be all right. Choose which way the lid is opened.—H. H.

**Electric Belt.**—T. P. J. (*Manchester*).—When I penned tbe reply to G. F. R. (*Woolwich*), which is printed on page 827, Vol. II. of WORK, I thought I had rendered all things as clear as could be desired in the small compass of a reply in "Shop," and I think G. F. R. must have been satisfied, for he has not eomplained. One cannot go into all the details in a reply, or it would take up too much spaee. In your letter you have shown that you fully understood the instructions, as you yourself supply the details omitted. I hope others will do the same. Yes, the silk-covered wire to connect the dises are "to be cut into several lengths aceording to tbe number of dises, and eonnected by soldering from one disc to another, and so finish off at the extreme end ones, where it is then complete as an eleetrie belt." The soldering ean be easily done with an ordinary soldering iron or soldering bolt when the discs are on the belt. Or you may solder the connections, and work them in as you proceed in sewing the discs to the belt. Take a zine dise, for instance, to form the extreme disc at the left-hand end of the belt. Clean it bright with emery-eloth, drop a mere trace of spirits of salts on the centre of the inside; bare and clean one end of a length of silk-covered wire; dip this into killed spirits, then solder it to the prepared spot on the zinc. Sew on the zine dise, pass the insulated wire out through a small hole made in the belt, and solder its other end to the inside of the copper disc to form one of the next pair; then sew this on the belt. The two dises to form one pair (outside and inside the belt, exactly opposite to each other) will not be thus eonneeted, as the eurrent will pass from one to the other through the thin flannel to whieh they are sewn when this is moistened with the sour sweat eoming from the body, or moistened with vinegar. I may mention here that the copper dises will be more effective and lasting if they are thickly electro-plated with silver. Now, when the whole number of discs have been eonnected as above directed, you will find one zine left out at one end of the belt, and one copper at the other. Connect the eopper to one part of a metal clasp sewn on the belt at one end, and the zine to the other part of a metal elasp sewn on the belt at the other end. The elasp may be made of any metal you may choose, and the two parts may be eonnected by a short piece of ehain if you wish to let out or take in the belt; but they must be thus eonnected by a metal conneetor of some sort to complete the circuit around the body. When the discs are all sewn on, you may cover the whole with thin flannel, and thus form a belt of triple thickness. The belt should be worn next the skin. Whether a current of electricity thus eontinuously passing around a person's loins has any beneficial effect on the liver and kidneys, or not, is more than I can say. A belt made as I have directed in No. 103, page 827, Vol. II. of WORK, will generate a current of electricity when the belt is moistened between the discs with sour sweat or with vinegar. This is all I can undertake to prove.—G. E. B.

**French Medieal Coil.**—F. G. B. (*No Address*).—The coil of which you send a sketch is a compact form of medieal eoil, enclosed in a box together with a Marié Davy battery of two eells, a receptacle for bottles, and another for the various electrodes employed with medical eoils. The battery cells are fitted with carbon plates at the bottoms; over these is spread a layer of sulphate of mercury. The cells are filled with water, and the zine plates lie in a horizontal position just beneath the surface of the water. At the right-hand side of the cell, next the letter N, the zinc plate rests on a platinum lug; and this is eonnected with the bushed hole marked N. This is the positive plate of the battery and its negative pole. The carbon plate at the bottom of this cell is connected to a platinum lug in the next cell, on which one end of the next zinc plate rests. The carbon of this cell is connected to the bushed hole marked P; and this is the positive pole of the battery. To connect this with the coil, make some brass plugs to fit in the bushed holes, and attaeh flexible connecting cords or lengths of insulated wire to the plugs. This done, connect the battery by means of the plugs and wires to the terminals of the primary coil (one going to the break pillar), and the coil should then work. The intensity of the eurrent is regulated by sliding on or off the two outside coils; when these are on, and the wires are attached to the bushed holes in the eoil ends, the maximum effeets are experienced. In this way you may get the powers from either one or two coils. The handles are made of wood to insulate the medical practitioner from the current whilst employing the selected electrode on his patient.—G. E. B.

**Hot-Air Engine.**—R. S. H. (*Calne*).—A friend of mine has a hot-air engine of two man-power at the brake; it indicates five man-power, so it uses up three man-power to work itself. It has a piston 9½ in. in diameter, stroke 7½ in; its fly-wheel is about 3 ft. diameter, and the centre of shaft about 5 ft. high. This will show you what a bulky affair it is; also it requires water to cool the eylinder. You must have a tank, or a continuous current through the casing, to keep it cool. A hot-air engine advertised as two man-power would very likely have a 7 in. piston, and give out one man. They are very easy to manage, very convenient, except that they take so much room, soon started, say, in fifteen minutes, but they are expensive. Messrs. Bailey, of Salford; Hayward, Tyler & Co., Queen Victoria Street, London; and Messrs. A. E. and H. Robinson, of Albert Square, Manchester, make hot-air engines. —F. A. M.

**Repairing Accumulators.**—W. J. D. (*Manchester*).—If the plates are all in good condition, and the cells are tolerably free from patches of paste from the plates, you may remove the old acid, and re-eharge the cells in the following manner: First eharge the plates up to tbeir full eapaeity, to prevent injury to the paste by air aetion. Then draw off all the acid by means of a syphon made out of 3 ft. or more of ⅝ in. or ¾ in. vulcanised indiarubber tube. Fill tbe tube with dilute acid, stop both ends with the thumbs of each hand, lower one hand below the surfaee of the liquid in the eell, and hold the end of the pipe there whilst both thumbs are withdrawn at the same instant. When the syphon has started drawing the aeid, lower the inner end to near the bottom of the cell, so as to draw off all the old acid. This done, fill it up at once with the new acid, and thus finish eaeh cell before emptying another. If the plates need repair, the whole set must be lifted out of the acid for the purpose, and replaced when repaired in the fresh acid. We eannot oblige by answering letters "next week," as next week's paper is made up and in the press when letters arrive.—G. E. B.

**Medical Batteries.**—DERNAX.—The following are makers of electro-medieal apparatus. From them you may seleet one to suit your requirements. Messrs. Woodhouse & Rawson, 88, Queen Victoria Street, London, E.C.; Messrs. O. Berend & Co., 61, Fore Street, London, E.C.; Messrs. Eidsforth & Mudford, Jackson Road, Holloway, London, N.; Messrs. G. Cohen & Co., 60A, Market Street, Manchester; Messrs. Salt & Sons, 21, Bull Street, Birmingham. Batteries are made and sold by Messrs. Cathcart & Peto, 57B, Hatton Garden, London, E.C.; F. C. Allsop & Co., 165, Queen Victoria Street, London, E.C.; and Messrs. T. Gent & Co., Faraday Works, Leicester.—G. E. B.

**Rolling Curtain for Optical Lantern.**—OVICE wishes to know how the wooden frame for ic rolling curtain is attached to the stage plate. will generally be found sufficient if the frames mply slide stiffly on to the supporting pillars of e slide stage, as it will then be an easy matter to move them if necessary at any time. If you articularly wish them to be a fixture, you can drill couple of holes through the stage plates in such a osition that a short screw can be driven into the de of each frame from the back, as shown at A in ie accompanying diagram. Care must, however, e taken to see that the screws do not interfere with the sliding of the curtain shutter along the grooves in the frame. In order to attach your portrait combination to the draw-tube of the lantern front, you will require to braze

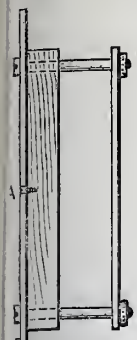


Fig. 1.

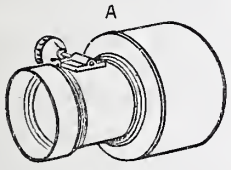

Fig. 2.

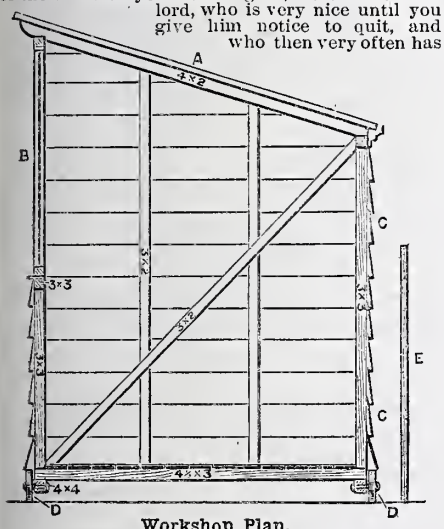
Rolling Curtain for Optical Lantern.

an ordinary O. G. brass flange (to be obtained from any lantern manufacturer) on to the end of the draw-tube, as shown at A in Fig. 2. The opening in the flange must, of course, be furnished with a suitable thread to take the thread of the lens mount; or, better still, the thread can possibly be removed from the present flange of the lens, and then soldered into the flange of the lantern front. If you do not possess a lathe, you could possibly get a job like this executed by Mr. Platt, Birkbeck Works, Kingsland, N.E.; or Messrs. O. Noakes, of Nelson Street, Greenwich.—C. A. P.

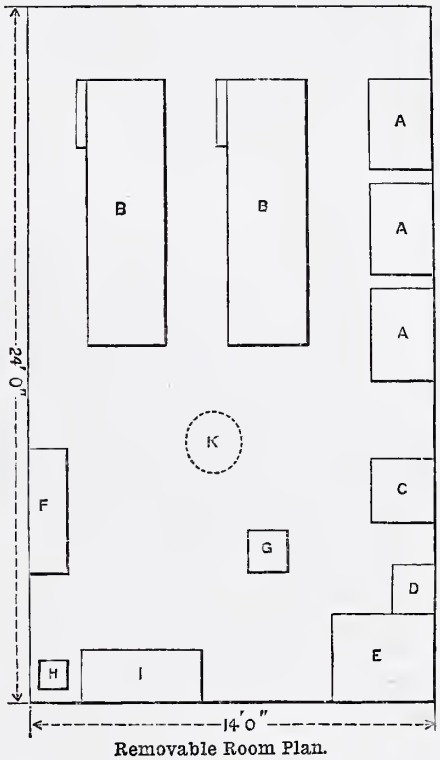
**Workshop Plan.**—N. M. (*Norwich*).—If, as you state, you wish to be able to remove your workshop in the event of moving, I certainly should not utilise the garden palings for part of the height, and most decidedly not let uprights into the ground. There are several things to be considered in matters of this kind; the first and most important for the time being is that very nice person "the next-door neighbour," who has a knack of determining for his own satisfaction the proper angle of light he is entitled to. Not but what he would have a very just cause for complaint if you did as your sketch shows you are inclined to do—viz., make his garden the receptacle for the water off your roof. Again, there is the landlord, who is very nice until you give him notice to quit, and who then very often has



Workshop Plan.

the same propensity for considering his own interests, and for keeping on his property anything to which he has the least claim, or may be beneficial to him, and causing to be taken away anything that may be the reverse. Below you will find a section based on the same lines as your own, showing what I should advise. I think this will at once explain itself. The two most important points are:—Firstly, the gutter, which you should lead down with a down-pipe to deliver on to your own property, and let it empty itself if possible into a gully, or else form a tank let into the ground; you will notice that I put the structure upon wheels, much after the style of a contractor's office. If you build it up a few feet away from its intended position, and then wheel it into its place, it would then, I think, take a very long stretch of imagination to call it a fixture. When you have it in its place, I should advise you to lever it up one corner at a time, and block it, keeping the wheel off the ground, having previously thoroughly greased with tallow the wheels and bolts, so that should you wish to demonstrate to anyone at any time that the structure is not a fixture, it would be an easy matter. This will give you a good air space underneath, and prevent your floor from rotting. You would find having tongue-flooring a great boon, as it would keep out the draught; and I should recommend some coarse wire netting between the sleepers and ground, to prevent cats from getting under. As to the cheapest material, the most suitable thing is sound yellow deal. If you frame the carcase together, and secure the tenons in the mortises with coarse screws, I do not think anyone will be able to prevent you from taking it away, and you will likewise be thoroughly independent. Should there be anything you do not understand, do not hesitate to ask again. I am very pleased to hear you have made a lathe out of an old machine stand, as not only does it show great ingenuity, but I am sure you must find it very useful.—E. D.

**Removable Room.**—J. C. (*Scarborough*).—Below you will find sketch plan of what you wish. You will notice that I have not given any more space between the lathes, benches, etc., than is absolutely necessary, and have allowed no room for materials, plant, or vice (which latter I think you would find almost indispensable), and yet your room has attained quite formidable proportions—viz., 24 ft. by 14 ft. In fact, there are some people who would call it a factory. I should advise your



Removable Room Plan.

making inquiries as to insurance, etc.; and if after this you still adhere to your original intention, kindly send rough plan of house and grounds, showing site upon which you propose to erect room. State likewise the stipulations laid down by insurance and surveyor—that is, if it comes within the jurisdiction of the latter. I shall then have much pleasure in going into details. Casually I may say that on the face of it it seems to me that brick or concrete and iron, not match-lining and iron, should form the foundation, etc., of the structure. I think you will agree with me that these particulars are a primary consideration.—E. D.

**Bamboo Canes.**—INQUIRER.—Bamboos may be bought in London from F. Westbury, 183, Gt. Dover Street, S.E.; from Benjamin & Co., 168, Great Dover Street, S.E.; from W. and T. Elmore & Sons, 16, City Road, E.C. London is the chief market for this material, and perhaps INQUIRER will do as well by sending his order there, though a Manchester or Liverpool directory would doubtless give him the name of a nearer dealer. In Vol. II., page 177, No. 63, he will find full details as to varieties, sizes, prices, etc.—M. M.

**Sable Writing Pencils.**—SOUTH AFRICA.—A reliable maker is J. B. Smith, 117, Hampstead Road, London, N.W. But makers are not always so expert at selecting as experienced users of pencils, who can tell their fitness with such critical accuracy. As you may want only a few selected ones of a sort—sable for writing, camel for lining, ox-hair, fitch, ichneumon, for other uses—you might try a selecting factor: in London, C. Witham, 22, Grove Street, Lisson Grove, N.W.; in Paris, Walter Lodia, 21, Avenue de l'Opera.—J. C. K.

**Cartridges.**—R. E. A. (*Sheerness*).—You do not say if ball or blank cartridge. If blank, the Martini cartridges answer. A Sheerness gunsmith will get what you require, if in small quantities; if large, Adams & Co., New Oxford Street, W.; Eley Brothers, London; or Kynoch & Co., Witton, near Birmingham. Prices vary for large or small quantities.—J. C. K.

**Arches.**—G. S. W. (*Walford Heath*).—If you refer to page 361, No. 75, and page 428, No. 79, of WORK, you will see the methods of drawing five different forms of arches, from which you will see how the radius is found. The centres are formed of ribs made of 1 in. boards, as shown in Fig. 1; the ribs are fixed 2 ft. or 3 ft. apart, and laths 1 in. or 1¼ in. thick nailed upon them, on

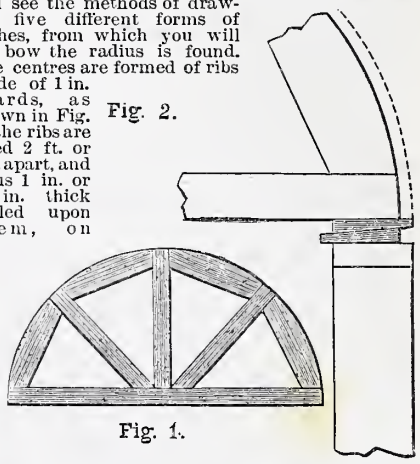


Fig. 2.

Fig. 1.

Arches. Fig. 1.—Rib for Centre. Fig. 2.—Method of fixing Centre.

which the arch is turned. They must be fixed on strong supports with double wedges under each rib, as shown in Fig. 2. These are for arches up to 8 ft. or 10 ft. span. If wider than this, the centres must be made correspondingly stronger, and bolted together.—M.

**Buckled or Bent Hand Saw.**—W. C. (*Stone*).—You should have stated how and in what place his saw was bent. As you have not done so, I give a rough sketch or two, showing, by hammer marks, how and where the saw should be struck, should it be as represented in either of the annexed sketches. W. C. must be very careful, and not deliver heavy blows. The plate of a hand saw being thin, requires a much lighter blow than saws of stout

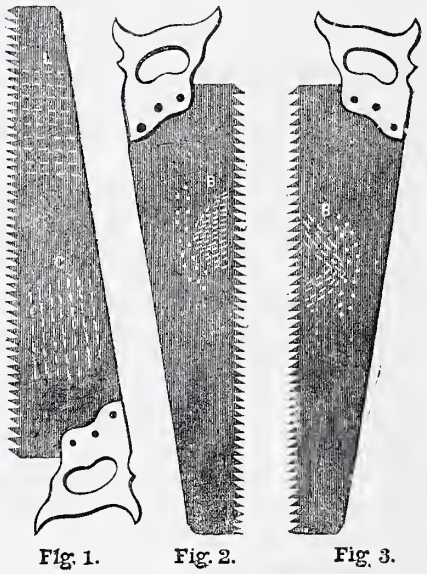

Fig. 1. Fig. 2. Fig. 3.

Buckled Saw Repairs.

gauge. If the blows are given too heavy, they will indent the plate, and at the same time stretch it more than is needful, and in consequence, a bad matter will be made worse. Fig. 1 represents a saw undulating, or wavy, lengthways of the plate at L, and bent or seamy across the plate at C. It will be seen that at L the blows are delivered across the plate, and at C lengthways of plate. The hammer to be used should be a cross-faced hammer. Figs. 2 and 3 represent a saw that has a bend at the edge; in this case the cross-faced hammer should be used on the convex side, as at B, Fig. 2, and on the concave side, as at B, Fig. 3; after which, it should be struck very lightly with the dog-head hammer, as indicated by round marks on both sides. In place of the dog-head hammer, the ordinary carpenter's hammer will answer the purpose by grinding the head a little convex.—A. R.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Electric Gas-Lighter.**—ELECTRIC SPARK writes:—"Can any contributor to 'Shop' inform me how to make the above on most approved form?"

**Galvanometer.**—GALVANIC writes:—"Would anyone kindly give me full instructions how to make a cheap, but good, galvanometer for experimental purposes? The Tangent, recently described in WORK, is too complicated; one of simpler construction would interest many readers."

**Photography.**—BOY-SORTER would like to know "(1) where is the best place to buy a camera for about 10s. 6d.; (2) also the simplest book for beginners; (3) which are the best dry plates to use?"

**Battery Troughs.**—M. H. M. (*Hull*) writes:—"Can any reader inform me if a small hole, sufficient to allow one cell in a trough battery to fill from another, would short-circuit the cells to the weakening of the current?"

**Autographic Ink.**—ON-TIME writes:—"How is an autographic ink made for draughtsman's drawings, from which reproductions can be made at letter-press machine?"

**Spring Mattress.**—APEX writes:—"Some time since, very good instructions for making a spring mattress were given. Will someone kindly inform me where I can obtain the springs, fibre, etc?"

**Soldering Pewter.**—APEX writes:—"Will some practical hand let me into the secret of soldering this metal? With all others I have been fairly successful, but have utterly failed in this."

**Wax.**—CARVER writes:—"I am at a loss to know where to get wax suitable for modelling a panel previous to carving in wood. I shall be glad if any reader could inform me through 'Shop.'"

**Treadle Knife.**—CUTTER writes:—"Would any reader kindly furnish me with particulars of a contrivance for attaching to a treadle grindstone (stone 25 in. in diameter) for the purpose of grinding a guillotine knife 20 in. long? Drawing would oblige."

**Braces.**—W. B. (*Preston*) will thank any reader to inform him where he can purchase wholesale quantities of indiarubber web, rivets, and rings for brace-making.

**Sewing Machines.**—SEWING MACHINE asks where he could get a book entitled, "The History of the Sewing Machine," by N. Salaman, who is also the writer of "Elias Howe's Biography" (London, 1863). Also Green's translation of Dr. Herzberg's work (1864) on the sewing machine.

**Draught Table.**—M. P. (*Manchester*) will be obliged for design, with size and working drawing, for draught table, suitable for two gentlemen.

**Sealing-Wax.**—J. C. (*Chelsea*) writes:—"Will any reader inform me the way to make white sealing-wax? Also, is there any white stain that will sink into hard wood and bone, and where I can get it?"

**Quartz and Grindstone.**—SINE CERA writes:—"Will any reader of WORK kindly inform me where I can obtain crushed quartz? It is required for covering buffing hands for buffing up spokes, etc. Also could you inform me the proper speed at periphery of grindstones?"

IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Clay Mixture.**—M. (*Bishop Auckland*) writes, in reply to HEATHFIELDS (see page 110, Vol. III.):—"These are called cob walls, and are built of a mixture of clay, loam, and chopped straw. The walls are made about 2 ft. thick, and are built on stone or brick foundations 2 ft. above the ground level. The material is kneaded into a stiff mass, and is built in layers, one layer being allowed to stiffen before another is laid on. The face of the wall is pared level with a sharp spade or parer, and is coated with plaster. The top of the wall must be well protected from rain. In some places it is built in frames similar to concrete walls (see page 60), small gravel being mixed with the clay, and is called Pisé work."

**Gas Engine.**—M. (*Bishop Auckland*) writes, in reply to H. R. P. (*Nottingham*) (see page 112, Vol. III.):—"You can obtain working drawings of these from Mr. A. Holmes, 127, Clowes Street, Hyde Road, Manchester. I do not know whether he supplies the castings, but if you write him he will tell you."

**Teasing Hair.**—E. W. C. (*Leicester*) writes, in answer to A. A. (*Edinburgh*) (see page 142, Vol. III.):—"There is, I believe, no machine that will tease horse-hair at the rate mentioned. There is a machine made by a Manchester firm called a 'devil,' which is made with a large wooden drum studded with steel points, but it is useless for hair. As everybody knows, the beauty of horse-hair is its length and curl. The machine I have mentioned breaks it into short bits, but is very useful for wool and flocks. The only way to open new hair is by hand, which is the best way for all kinds of hair; but for old hair there is what are called 'cards,' which consist of two boards covered with a kind of leather, and studded with a sort of square wire staple, with the points bent to an angle of about 45°. The bottom board is fixed, and the top one is worked with the two hands, by the aid of which from twenty to thirty lbs. of hair per hour can be accomplished. These 'cards' can be obtained from any upholsterer's warehouse in Old Street or Curtain Road, London. If A. A. thinks it will pay him to make one—which I douht—I will send more particulars."

**Scrap Leather.**—G. P. (*Fulham*) writes:—"If A. F. W. (*Oldham*) (see page 829, Vol. II.) will offer his scrap leather to Geo. Ives, Wakefield, Yorks., I think he will get a much hetter price than from the two firms mentioned on page 46, Vol. III., by J. M. (*Manchester*)."

**Fish Stuffing.**—F. H. (*Streatham*) writes, in answer to F. M. (*London, N.W.*) (see page 110, Vol. III.):—"I would advise F. M. to practise upon a tough-skinned fish, such as the perch or a pike. First note all the peculiarities of shape and colour; it is a good plan to make a water-colour drawing of the subject. Select the hest side of the fish, and cover it with tissue-paper or muslin; this keeps the scales fast in their seats during the skinning. You must he sure to keep the fish damp during the operation. Lay the fish the worst side uppermost on a board, then cut the skin from head to tail in a straight line; cut through the large bone heneath the gills with a strong pair of scissors. With a broad knife in one hand, and holding the skin lightly with the other, with a scraping motion of the knife carefully separate the skin from the flesh. Be careful at the fins; cut them deep, leaving a part of the flesh on. Work towards the tail, and remove the skin round the tail with the fingers; cut the bone and flesh completely through with the scissors about 1 in. from the last joint of the vertebra. Now work the skin off round the head, and with a knife sever the bone near the head. The skin now being free from the hody, scrape away all the small pieces of flesh that are still adhering to the inside of the skin, and around the fins and tail. Now turn your attention to the head. Make a cut along the side of the under jaw, cut away the gills, clear the head of all remaining flesh, take out the eyes, and he careful not to eut your fingers with the small bones. To stuff the fish, procure a thick piece of wire somewhat longer than the hody, bending one end to form a large oval-shaped loop, to be placed into the head, the other end to be pointed to push into and support the tail. This wire is to form an artificial back-hone, and must he such a length as to allow one end to go through the centre of the bone in the tail; form two loops on the wire to support the hody on the hack of the case when finished. Now wrap round the wire some paper, tied with string, until it is a little less than the hody that is taken out, and make it somewhat the shape of the fish without head or tail. When this is done, cover it with tow tied on with hemp. Lay this down, and thoroughly anoint all parts of the fish. Stuff out the now hollow sides of the face, gums, and the underneath of the throat with putty, of which push some thick pads underneath the root of the tail. Next lay a thin skin of putty over the whole of the skin on the inside. The next thing to he done is to insert the hody. Pushing the sharpened end of the tail wire through the hone of the tail, fix the loop in the head, and commence to sew the edges of the skin with needle and thread, shaping the fish as you go along. A little gentle tapping with a small piece of wood will bring it into shape. Bore two holes in a board for the supporting wires, and carefully turn your fish over, to examine the show side. Gently press the skin with the hands; now go over the whole of the outside of the skin with a carbolie wash:—Glacial carholic aeid, 2 oz.; hurnt alum or pure tannin, 1 oz.; water, one pint. Keep in stoppered bottle lahelled 'Poison,' and shake up heforc using. Place all the fins in their position; the head will require a great deal of attention. It is now flat, and, perhaps, drops down upon the board. To obviate this, prop the nose from the underneath by a piece of cork. The mouth may he kept open as much as desired hy wire. The fins must be 'braced out' on flat pieces of cork with pins. Let the fish be now put hy in a moderately warm situation to thoroughly dry. When it is thoroughly dry, the skin will be like leather, with no colour in it at all, and must, of course, be subsequently coloured up according to nature—the eyes put in with wax. The fish should now he varnished with spirit varnish, and mounted in a case with appropriate water-weed. The fish should be coloured with oil-colours, such as are used by artists, thinned with turpentine."

**Mandrel Head.**—TURNER writes, in reply to H. M. (*Maiden Newton*) (see page 142, Vol. III.):—"Whatever you do, do not on any accouut run your mandrel in east iron. I worked a lathe for three days running, in hot June weather, which had cast-iron hearings all over, and I might just as well have heen on a tread-mill. The cast iron gets hot with the friction, and, consequently, the mandrel 'binds.' Brass hearings would do, hut hardened steel is the proper thing, though troublesome to true up. I am now myself engaged on a new lathe spindle of my own design, hard steel wearing parts so arranged that you may take all play out, and yet have it run freely. I hope to have it finished a fortnight hence." [TURNER may send in his drawing and description on approval.—ED.]

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—A FRETWORKER; W. H. W. (*Great Yarmouth*); QUÆSITOR; J. B. (*Manchester*); T. A. (*St. Helens*); F. D. B. (*Newcastle-on-Tyne*); O. M. (*Barrow-in-Furness*); A CARTWRIGHT; G. H. (*Camberwell*); LEGHORN; H. R. (*Clapham*); R. W. (*Bow, E.*); H. J. (*Rochdale*); TEVIOT; H. E. B. (*Cheshire*); BICYCLE BUILDER; A. T. B.; A. W. (*Paisley*); J. H. (*York*); F. P. (*Swansea*); C. D. (*Glasgow*); INCUBATOR; H. R. M. (*London*); J. S. (*York*); A. M. (*Putney, S.W.*); ARTIST NOVICE; B. F. E. (*Carlisle*); ANXIOUS; RAYNOR; P. P. (*Harrow*); TOXTETHIAN; R. H. M. (*York.*); H. MCG. (*Kilmarnock*); T. B. B. (*Manchester*).

# THE JOURNAL OF DECORATIVE ART

(Monthly, *7d.*).

A JOURNAL devoted to the interests of

PAINTERS AND DECORATORS,

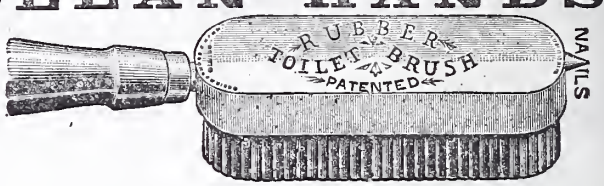
and to the furthering of DECORATIVE ART in the home.

SPLENDIDLY ILLUSTRATED.

Send *9d.* for Specimen Number to

W. G. SUTHERLAND, 15, ST. ANN'S STREET, MANCHESTER.

# CLEAN HANDS!



*For Everyone, no matter what the Occupation.*

Nothing has ever been invented that will so thoroughly cleanse and whiten the hands as our **Rubber Brush.** Used with soap and water, it will remove all kinds of stains. **Ink, Tar, Iron Stains,** and **Paint,** yielding easily to it, without injuring the most delicate skin, as is done by using pumice stone, bristle brushes, &c.

Price 1s. Larger Size, price 2s.

We are also the makers of BAILEY'S CELEBRATED RUBBER BATH and FLESH BRUSHES, price *5s.* each; COMPLEXION BRUSHES, price *3s. 6d.* each; RUBBER TOOTH BRUSHES, price *10d.* and *1s.* each; and TEETHING RINGS, price *5d.* each.

*To be had from all Chemists and Dealers in Toilet Goods, or will be sent, post free, on receipt of price by the Manufacturers.*

DAVID MOSELEY & SONS, 14, Aldermanbury Avenue, London, E.C.; Ardwick, Manchester; and 57, Miller Street, Glasgow.

# THE WORLD'S WORKERS.

*A Series of Original Volumes by Popular Authors. With Portraits printed on a Tint as Frontispiece, cloth, 1s. each.*

General Gordon. By the Rev. S. A. SWAINE.

Sir Henry Havelock and Colin Campbell, Lord Clyde. By E. C. PHILLIPS.

David Livingstone. By ROBERT SMILES.

The Earl of Shaftesbury. By HENRY FRITH.

Dr. Guthrie, Father Mathew, Elihu Burritt, Joseph Livesey. By JOHN W. KIRTON, LL.D.

George Müller and Andrew Reed. By E. R. PITMAN.

Thomas A. Edison and Samuel F. B. Morse. By Dr. DENSLOW and J. MARSH PARKER.

Sir Titus Salt and George Moore. By J. BURNLEY.

George and Robert Stephenson. By C. L. MATÉAUX.

Charles Dickens. By HIS ELDEST DAUGHTER.

Handel. By ELIZA CLARKE.

Turner the Artist. By the Rev. S. A. SWAINE.

Abraham Lincoln. By ERNEST FOSTER.

Benjamin Franklin. By E. M. TOMKINSON.

Dr. Arnold of Rugby. By ROSE E. SELFE.

Sarah Robinson, Agnes Weston, and Mrs. Meredith. By E. M. TOMKINSON.

Florence Nightingale, Catherine Marsh, Frances Ridley Havergal. Mrs. Ranyard ("L.N.R."). By LIZZIE ALLDRIDGE.

Mrs. Somerville and Mary Carpenter. By PHYLLIS BROWNE.

Richard Cobden. By R. GOWING.

## ON COLOUR APPLIED TO FORM.

BY FREDERICK PARSONS, F.S.Sc.

INTRODUCTION—TINTING THE CORNICE—ELASTICITY OF TERM—INDIVIDUAL TASTE—COLOUR, A SCIENTIFIC AND ARTISTIC SUBJECT—OWEN JONES ON COLOUR—RUSKIN ON COLOUR—CHROMATIC EQUIVALENTS OF CHEVREUIL AND FIELD—EXPRESSIONS OF PRIMARY COLOURS—CORNICES ON OWEN JONES'S THEORY—SUGGESTED TREATMENT OF BEDROOM CORNICES—CORNICE FOR DINING-ROOM—CORNICE FOR DRAWING-ROOM—GENERAL RULES FOR TREATMENT OF CORNICES.

LET not the intelligent reader start, nor his countenance grow troubled, on seeing my head-line, since the purpose of this paper is of both a simple and practical nature. No mystical theories of "luminiferous ether" or "wave-lengths" are about to be considered; nor am I desirous to "trot out" those items of interminable discussion—the ancient polychromatic treatment of classic statuary, or the truth and beauty of mediæval applications of colour to stone mouldings, tracery, and panel-work. Those who want a strong dish of "scientific colour" must turn to the recent works of Professors Ogden Rood or A. H. Church; whilst it would ill become one to consider in WORK the latter aspect of colour applied to form—"the form divine"—when all the skilled and learned Fellows of the "R.I.B.A." are fervently enthusiastic in their divided opinions.

"The cornice to be tinted to match." This is a harmless-looking sentence that appears on nearly every specification of modern house and decorative painting. There are many readers of this paper who, doubtless, "could a tale unfold" concerning that apparently simple operation which, if not so harrowing as that related by the ghost in *Hamlet*, would so reek of worry, nervousness, and mortification of spirit that they here greet with gladness any attempt to explain the practical aims and methods by which this tinting of cornices is successfully governed.

It is a remarkable fact that, whereas even

ten years back tinting to plaster cornices was seldom undertaken beyond the reception-rooms, nowadays it is common, in all the chief centres of trade, to every decent bedroom of a house of any pretensions. The great expansion of our notions of home and industrial art has chiefly accounted for this; but a greater stimulus has been directly derived from the "fashion"—educated demand—for the beautiful effects of *colour* that is now current. Instead of the old orthodox "grey-satin" wall-papers, with their white-washed or "water-wave" papered ceilings, we have "blue bedrooms," "red," "old gold," or all these primary tones combined in one design of wall-paper; whilst the ceilings have ornamental designs to correspond in paper-hangings, or are distempered in a decided tint of pink, cream, or blue. To leave the cornice white, or even the same as the tint of ceiling, looks altogether weak and poor; and here it is that the worker, unless he has both colour ability and experience to guide him, often finds his peace of mind forsake him.

This "tinting," as applied to plaster cornices, is a somewhat elastic term. It may mean the application to the whole of its members of one general "tint" of colour with white, or the addition to this of a few beads and lines of positive colour; or it may be further interpreted as colouring the cornice with various and many colours and tones, to harmonise with or contrast the wall or ceiling decoration.

Now, when a woman—or the average woman—chooses a coloured ribbon or dress material, she is usually guided in that choice by her own individual "taste." This selection by "taste" is in many respects a very curious phenomenon. "I know what I like!" is usually the sole justification of colour choice. If one were to inquire the why or wherefore of the decision, the only resource that avails is "Taste—my taste!" Should the object of discussion be a carpet, curtains, or wall-paper, we usually find the same operative power in force. So long as one person's colour "taste" has but to please the author of it, this kind of irrational and irresponsible selection may work very well; but if the *decorator* desires to conceive a scheme of colour that shall stand criticism and merit general approval, he must work on totally different lines.

*Colour* is, in itself, both a scientific and an artistic subject—scientific, for instance, in its dependence on and relation to the sense of vision; and *artistic* in that its effects are capable of "individualism" in manipulation, and of conveying definite sensations and emotions of truth and beauty from the mind of the colourist to that of the beholder. We may fairly class the art of the colourist upon the same level as the art of the musician. What, therefore, should we think of any person's "taste" in pianoforte playing which simply consisted of strumming haphazard certain strings, without any regard for or knowledge of the laws of harmony and concord? And yet this is, if anything, a less questionable matter, since that instrument gives us *fixed* tones, while with colour we have no similar permanent scale to work upon. One would further imagine, judging from every-day experience, and an occasional dip into the "Home Art" column of a Society paper, that "colour taste" is inherent in nearly all human nature. If that is to be seriously accepted as a correct standard of selection, we can only rejoin by pointing to the interesting inhabitant of the Cannibal Islands, whose physical palate, according to this argument, is equally a natural and "good taste," since it is "his taste."

Notwithstanding forty summers have come and gone since John Ruskin, and that eminent architect and decorator the late Owen Jones, boldly controverted each other's teachings on the relation of colour to form, the force and application of their "old-time" contentions are still to-day of much interest and value. We will, therefore, briefly consider those conflicting arguments, and endeavour to see how far they supply a basis for practical work, such as tinting cornices and other simple decorative arrangements of colour.

The Marlborough House lectures of Owen Jones, given in the year 1852, contain this dogma or proposition:—*Colour is used to assist in the development of form, and to distinguish objects, or parts of objects, one from another.* In general support of this, the lecturer referred to Nature, and pointed out the difference in colour between flower and stalk, the appearance of earth and sky, and of the hair, eyes, etc., of the human figure.

Mr. Ruskin's theory, which he also deduces from the observance of natural colour, is that colour never follows form, but is arranged on a totally different system. He argues—"What mysterious connection is there between the shape of the spots on an animal's skin and its anatomical system? The stripes of a zebra do not follow the lines of its body or limbs, still less the spots of a leopard;" and in sequence to these and other natural examples he concludes—*that the first great principle of architectural colour is this: let it be visibly independent of form.*

Although even a bare statement of these two diverse conclusions should be valuable to all young students in architectural or decorative colour, I do not intend here to further explain or analyse them. The period of time that has elapsed since the above lectures and that wherein we record our own humble experiences has shown much progress in decorative art and colouring, so that modern conclusions concerning the relationship of colour to form are now on this wise:—*That the two systems, whilst being quite distinctive and separate, may be so combined as to materially enhance the beauty and effect of both.*

Now, let us assume, for the purpose of practical illustration, that the early chromatic equivalents of M. Chevreuil and George Field are correct—viz., that the *primary*, or first, colours are pure red, pure blue, and pure yellow; that each primary is contrasted harmoniously with, or neutralised by, a mixture of the two other primaries in certain proportions, which mixture is named a *secondary;* and further, that each secondary is balanced by a certain mixture of the two remaining secondaries, termed a *tertiary* colour. The total purport of this is, therefore: *primaries*—red, blue, yellow; *secondaries*—purple (red and blue), green (blue and yellow), and orange (yellow and red); *tertiaries*—olive (green and purple), russet (orange and purple), and citrine (orange and green).

The *expressions* of the primary colours—that is to say, the main impressions they convey to the mind through the vision—are, briefly, as follows. Red gives richness and warmth of sentiment, and appears stationary of position when applied to form. Blue speaks of space and coolness, and will give a retiring effect to form. Yellow conveys several sensations, and is most difficult to successfully manipulate: we consider it chiefly an exciting power, which may verge from high brilliancy and lustre to very gairish and irritating effects. Beyond this, in its application to form, yellow has a prominent or advancing appearance.

Here let us turn to Fig. 1, representing the section of a cornice used by Owen Jones to explain his theory. Red is placed in the shade to soften its brightness; yellow is put on the most prominent form to assist its shape; blue in the concave moulding. White intervenes between them on the vertical planes, to prevent one primary impinging on the other. This, it must be pointed out, is really but applying to mouldings the colours best adapted to displaying their shape; it does not secure colour harmony of the cornice in itself, much less of cornice with the supporting wall. We get an idea from Fig. 2 how far colour (represented there by shade) does assist form. At Fig. 1 we have them as above-mentioned; at Fig. 2, the colours reversed. *Colour harmony* is still independent of either arrangement.

At Figs. 3 and 4 we consider the tinting of ordinary bedroom and sitting-room cornices, respectively. The first of these assumes a bedroom of cold aspect, the walls hung with a paper in "self-tones" of light salmon-buff, the ceiling-flat being distempered a warm cream—white with *raw terra-di-sienna*. The mouldings next to the paper I put a warm, "mossy" green, made from ochre, umber, a little *ultramarine green* (a blue of very green hue), and a little white. The green hue must be very subordinate, since the warm walls will bring it out fully. In the cove I put a light tint of warm colour, which, by reason of the shade, will look a little deeper; this also is used on the flat A, next cornice. The mouldings between cove and flat are a lighter tint of the moss-green made with the latter, and the ceiling cream-colour. If handled with care and judgment, the result will be harmonious and effective with simply three tints of colour. The other example (Fig. 4) provides a neutral, or "warm," green, flatted wall-colour. Next to this we put a soft terra-cotta, or reddish-brown, a few shades darker than the wall; above this a band of wall-colour, and this framed by the previous terra-cotta at A and a lighter shade at B. The cove we put in a lighter and more yellow tint of the walls, bounded also on top by the lighter terra-cotta tint. A deep-cream flat comes next, then the ogee in a light tint of greeny-blue, which is separated by a small cream flat from a light and soft salmon-tint on ceiling.

Fig. 5 represents colour applied in a dining-room over a rich and glowing wall-paper of semi-natural floral design, the colours being warm greens and browns, with flowers in mixtures of soft, rich red, old gold, and a little "gobelin" or greenish-blue. We give the ceiling a soft but decided pink tint, made with Venetian red and ochre, and put an 8 in. margin, next to cornice, in a deeper shade of ceiling colour. The base of cornice is a medium bronze-green, the cove Indian red and a little white—deeper than the base in tone. The margin colour of ceiling is put on the flat above at X; a medium tint of soft gobelin blue at the flat and hollow next to the cove, and the remaining members warm buff and a greenish-yellow or light mossy green. The lines and ornament may be in terra-cotta, moss-green, and light gobelin blue upon the light pinky-buff of ceiling. In this section the place for a little gilding is indicated.

Fig. 6 is a treatment for a drawing-room having straw-cream ceiling and old gold

walls in self-tones (or monotones) of that colour. The blue cove tint, though appearing blue against a faint yellow and cream, is, when viewed alone, quite a green tint. The very faint pink reed-colour is a tint of Indian red. The creams are made with chromes and umber, and must not be at all irritating.

I do not wish to imply by this lesson that any worker who attempts to follow my directions will be sure to get the best results. He must have a mind that is sensitive to harsh or crude sensations, and that can avoid them. Beyond this, when dealing with the individual client, we may have to consider his or her colour-idiosyncrasy, which often exists in a natural dislike of one particular colour. In all cases, let the cornice *in its entirety* frame the ceiling. Let the darkest colour be at the base, and lighten up to the ceiling; but always get the deepest tones darker than the general wall-colour. In mixing distemper tints, accustom the mind to judging the effect of a colour when dry. Avoid all plain tints of white with pure red, blue, yellow, green, etc. Make up the various tones of colour in the pots; then put a little red into green, green into red, etc., until they are sufficiently soft and neutralised to give a restful and harmonious combined effect. Do not fritter time away in putting twenty colours and shades into one cornice; the client cannot appreciate it, and it is lost to ordinary view, besides destroying the breadth of the cornice. Never put gilding save on advanced portions, and always finish it off with a coating of clear size.

## THE VIOLIN: HOW TO MAKE IT.

BY J. W. BRIGGS.

NECK AND SCROLL—BLOCK FOR NECK—MARKING OUT—CUTTING OUT—TRACING SCROLL OUTLINES—CARVING SCROLL—FINGER-BOARD—CUTTING PEG-HOLES, ETC.—GLUING ON FINGER-BOARD, NUT, ETC.—CUTTING SHOULDER—FITTING NECK TO BOX—ROUNDING AND GLUING UP NECK—VARNISHING AND VARNISHES—FINISHING—SETTING SOUND-POST, STRINGING, AND SCREWING UP.

**Neck and Scroll.**—The neck is next wanted, and I will try to tell you how it should be made; but as regards the scroll, I fear you will have to depend more on your eyes and the patterns than on any description which I can possibly give. By all means have a good neck and scroll near you for reference and guidance.

*Block for Neck.*—The block from which the neck is made is a piece of sycamore $10\frac{1}{2}$ in. long, 2 in. broad, and $2\frac{1}{2}$ in. deep. The 2 in. side should be that nearest the bark of the tree. Plane this side true, and it shall be called the "face." Next plane both $2\frac{1}{2}$ in. sides true and with the same bevel from the "face," and saw one end square off. The block, when ready for use, should be $10\frac{1}{2}$ in. long, $2\frac{1}{2}$ in. deep, and $1\frac{7}{8}$ in. on the face side, with an end section like Fig. 17. It will be convenient at this time to make a centre line along the face, square it down each end, and continue with a straight-edge along the under side. If you are fortunate enough to get a piece 2 in. wide both top and bottom, your labour will be considerably reduced, as it will be much easier to make true or square cuts.

*Marking Out.*—I have assumed that Fig. 18 will be cut out, as well as preceding patterns, in zinc or thin wood. Your neck block being now ready, lay the pattern Fig. 18 on the block, and trace round it with the marker, pencilling afterwards; next square the line A $A^2$ across, and, $\frac{25}{32}$ in. from the top of this line, square from the end of the block the line B $B^2$; the intersection of these lines gives the proper position, or centre, from which to describe the eye of the scroll, which is done with the compasses opened to $\frac{5}{32}$ in., and making a circle from this centre. Three-quarters of an inch from A the line E E should be squared across. From a point midway between $A^2$ and B and crossing the centre draw line C $C^2$, and from midway between $A^2$ and $B^2$ draw line D $D^2$; now prick through the dots on the lines in the following order: A, C, $B^2$, D, $A^2$, $C^2$, B, $D^2$, and then through the second or outer dot on A. When a proper curve is drawn between each of these dots, the outline of the spiral is complete. Now square lines across the face at F H, and $5\frac{5}{8}$ in. from F the line I.

*Cutting Out.*—The outline may be cut out by a narrow band saw; for a few pence a sawyer will do this, and it is much safer than the bow saw. If the neck is being made from a piece like Fig. 17, a piece of deal, sufficiently thick to make the unmarked side lay square on the saw table, had better be glued on. After being sawed out, remove the remnants of the strip, and mark this side in a corresponding way to the other side. The centre marks will have been partially taken out by the saw, and the line must now be continued all round the head from F to G. Now square a line across the back at G. With the compasses open $\frac{3}{4}$ in., set out that distance each side of the centre line at I; close the compasses to $\frac{7}{16}$ in., and mark so much off each side of centre line at F, and with a pencil and straight-edge make a line over the marks on each side, but extend them to E. The sides thus marked out should be sawn down, and then cut square off at E.

*Tracing Scroll Outlines.*—Trace the scroll outlines, Figs. 19 and 20, in their places, as marked on the patterns. Open the compasses to $\frac{3}{16}$ in., and draw them down each side of the head from the end of line C to F; one point of the compasses will be at the side, and the other will mark out the cheeks of the peg-box, which, being thus described or marked, should at once be cut out with gouges and chisels. When this has been done, file the cheeks clean and square. Now fasten the neck edgeways in the vice, and with a dovetail or fine tenon saw cut down just outside the lines K K, L L, M M, N N, but not so deep as to cut into the lines marked from Figs. 19 and 20. Next saw at right angles with these cuts, and along the marks made from Figs. 19 and 20.

*Carving Scroll.*—The rough wood is now taken off, and with gouges of various shapes you should now be able, constantly referring to your model, to make a respectable scroll for an amateur. Accurate manipulation of the carving tools is not the only requirement before a good scroll can be made; a cultured eye is essential. When the scroll is carved, the head should be scraped and sand-papered, and thoroughly sponged over with cold water; this will throw up the defects. When it is quite dry, gauge, with the compasses opened $\frac{1}{16}$ in., lines all round the head and scroll. Between the gauge mark and the centre line, from G round to C, the hollows should next be carved. With a fine file bevel off the edges all round the head and scroll as far as the compass lines; now carefully sand-paper all over, leaving the edges of the bevels quite sharp.

*Finger-Board.*—The ebony finger-board—which, of course, you will buy ready made—should next, with the veneer plane, be planed true on the flat side, and have a centre line marked along it. The "face" of the neck should also be toothed over with the same plane, and the centre line be freshened up.

*Cutting Peg-Holes, etc.*—Place the neck pattern (Fig. 21) flush with the neck and to the marks F and I, and trace firmly the lines O O, P P P, and also make the four dots where the peg-holes will have to be bored. Repeat the process in corresponding position on the other side of the neck, and with tenon saw cut down O O, keeping square across centre mark at I. Now square the centre line down the face thus cut.

*Gluing on Finger-Board, Nut, etc.*—The finger-board should now be glued on (use only two or three drops of glue, as it must come off again before the fiddle is varnished), with the centre line coinciding with that on the neck, and the narrow end of the board touching the line H. The board being cramped fast with hand-screws, the nut should be glued on. It is a piece of ebony $\frac{1}{16}$ in. deeper than the thickest part of the narrow end of finger-board, $\frac{5}{16}$ in. wide and $\frac{15}{16}$ in. long. Both nut and board being quite set, which they will do much more rapidly if made hot before they are glued, put the neck, board downwards, in the vice, and cut just outside line P P P with the bow saw. This done, file down to the line, using a small straight-edge to try the evenness of the neck, between the curves.

*Cutting Shoulder, etc.*—Remove the neck from the vice, and place the shoulder pattern (Fig. 22) with the top side close under, and even with the edges of the finger-board, and mark down both sides and across the bottom of pattern. With a gouge, followed by broad chisel, cut to the lines last made, and also across the bottom at T (Fig. 21); along this face the centre line should next be squared. Fasten the neck in the vice, and cut off the parts which project over the finger-board, and with files make both the neck and nut even with the finger-board.

*Fitting Neck to Box.*—If the instrument has been made true to the lines, there will not be much difficulty in fitting the neck. Place the neck with its back centre mark on the joint of the "tab" and the centre line of shoulder, coinciding with the joint of the belly. With a sharp knife make cuts *slightly narrower than the shoulder* in the end of the belly, and remove the neck. Extend the cuts to the inner edge of the purfling; lay a small straight-edge along the purfling, and cut out the rectangular piece of the belly between the shoulder-marks. Again put the neck in position, and with a very fine point trace the sides of the shoulder on the ribs, and cut through these lines into the block. With a $\frac{5}{8}$ in. chisel cut the block down to the belly, proceeding very carefully, frequently trying the neck until the true position is obtained. This must be tested by looking along the sides of the finger-board and between the sound-holes, up the back joint and along the centre line of the head, and along the edges of the back, with which the eye of the scroll should be in line. Now mark the shape of the tab on the back of the shoulder.

*Rounding and Gluing up Neck.*—The neck should next, with gouges, rasp, and files, be rounded to a rather oval shape

(for which I never use patterns), and thoroughly sand-papered. When this is done, it is the best time to bore the peg-holes, with a $\frac{3}{16}$ in. bit, from outside each cheek, with a wedge or block inside the peg-box to make it solid. Now run the taper bit through the holes as a finish. The holes nearest the finger-board should taper from left to right, the next two from right to left, and so on. Now "size" the shoulder, and glue the neck in its place. In a few hours wash the fiddle over to remove all glue and dirt, and when dry, finish the "tab" and give a final course of sand-paper, and the violin will be finished in the "white." It is hard to resist the temptation to string the fiddle up in this state, but to do so would cause a great deal of labour, so you had better remove the finger-board and get ready for varnishing the instrument.

**Varnishing and Varnishes.**—It is not my intention to enter into a disquisition on varnishing. Should the reader wish to study the question for himself, he has any amount of opportunity offered for doing so; and, in experimenting, he has a good chance of disposing of his surplus capital and spare time. Amongst the works offered for his assistance are those of Davidson, Otto, Hart, Savart, and others, as well as in Mr. Fleming's very readable book, "Old Violins." But I confess that nobody has impressed me so much as the late Charles Reade did in his letter which went the round of the newspapers some years ago. Whenever I have varnished a fiddle in the way named below, it has always been most satisfactory. It would be an impossibility for anyone to begin to varnish a fiddle without being compelled afterwards to make some experiment or other.

Placing a small quantity of Howard's essential oil of turpentine in a cup, I put the latter in a water bath on the gas stove, and, at a very gentle heat, dissolved as much gamboge as the oil would take up, and then laid a coat on the violin. In three hours, the first coat being dry, another coat was given of the same varnish. Two days afterwards the varnish was quite hard—a beautiful yellow; the grain had not risen, and was quite bright. Having a good foundation, I put coat after coat of varnish, composed of the saturated alcoholic solutions of dragon's blood, sandarach, and benzoin (rubbing each coat down with a piece of oiled felt), until the varnish was quite solid and brilliant.

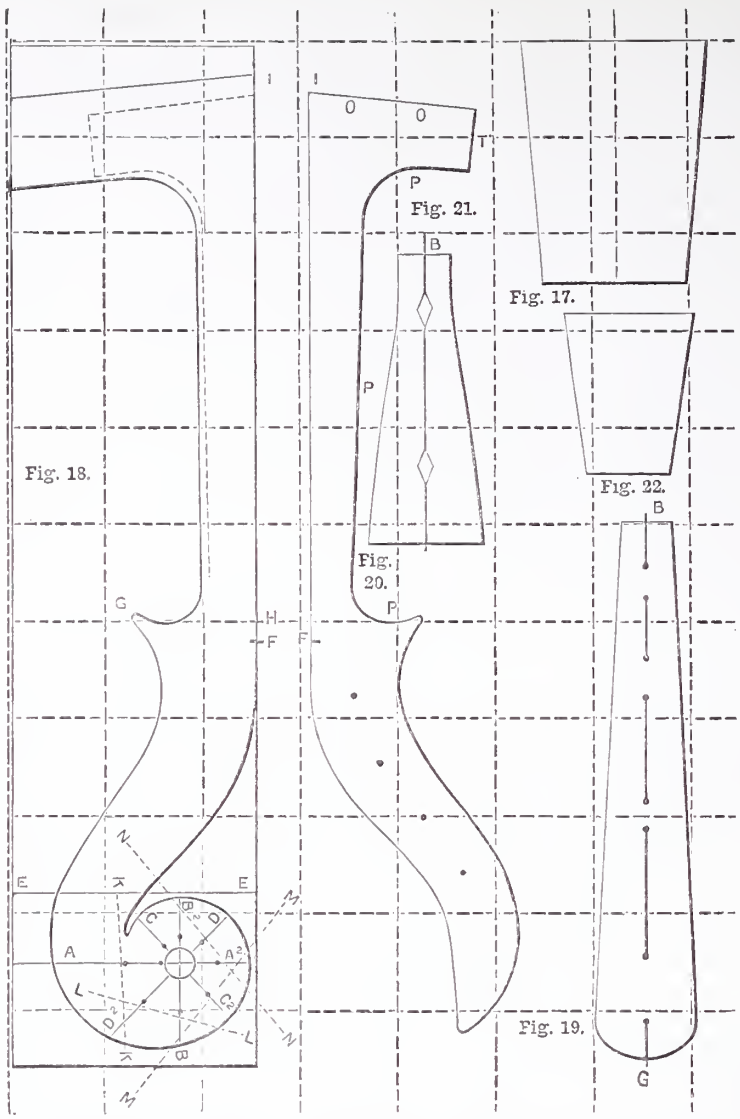

Fig. 17.—Section of Block for making Neck and Scroll. Fig. 18.—Pattern for making Neck and Scroll. Fig. 19.—Outline of Head (Back). Fig. 20.—Outline of Head (Front). Fig. 21.—Pattern of Neck. Fig. 22.—Pattern for cutting Bevel for Shoulder. All the above Figs. are half size, and divided into Squares for Enlargement to full size.

There are on the shelves in my work-room the saturated solutions of mastic, dammar, elemi, sandarach, benzoin, myrrh, dragon's blood, Socotrine aloes, Barbadoes aloes, gamboge, annato, seed lac, sandal-wood, saffron, Venice turpentine, etc. Appended are a few recipes for making varnish, which have been gathered from various sources.

(1) Dissolve in oil of rosemary as much clear copal as the oil will absorb. If too thick, use spirits of wine to dilute.

(2) Essential oil of turpentine, 8 ozs.; drying linseed oil, 4 ozs.; fused amber, 4 ozs.; gum lac, 1 oz. Dissolve by heat.

(3) Dissolve by heat 8 ozs. of copal in 1 pint of drying oil, and use oil of turpentine as a dilnent.

(4) Make a strong alcoholic solution of sandal-wood or other colour desired, and concentrate this solution by evaporating it to half the bulk. Mix the solution with essential oil of turpentine, and evaporate all the spirit by boiling in a water bath. To each gill of coloured essential oil add in turn, as dissolved, $1\frac{3}{4}$ ozs. of mastic, 1 oz. of dammar, and lastly, 1 oz. of linseed oil. This varnish should not be used until three or four months old.

(5) *Spirit Varnishes:* Gum elemi and mastic, $\frac{1}{2}$ oz. each; sandarach, 2 ozs.; Venice turpentine, 1 oz.; seed lac, 1 oz. Dissolve in 12 ozs. of methylated spirits which has been coloured to suit.

(6) Colour 1 pint of methylated spirit or wood naphtha to suit, and add the following: 2 ozs. of mastic, 1 oz. of seed lac, $2\frac{1}{2}$ ozs. of juniper, and 1 oz. of Venice turpentine.

(7) Three ozs. of shellac or seed lac, 3 ozs. of sandarach, 1 oz. of mastic, 1 oz. of benzoin, to each pint of coloured spirit.

**Finishing.**—The fiddle should be varnished, with the exception of the "handle" part of the neck, and when it is perfectly hard—not before—it will be ready to have the neck cleaned; which done, glue the finger-board on the neck again—this time quite fast. When it is set, wash all dirt and glue from the neck, and polish it up with the finest sand-paper and linseed oil; but mind that the varnish be not injured in doing this. With a fine "rat-tailed" file cut in the nut the four grooves in which the strings are to lay. Mark the positions of the outer grooves $\frac{1}{4}$ of an inch from each end of the nut, and, with the spring dividers, divide the intervening space into three portions. Make all the grooves free from sharp edges, as these would cut the strings. Free the peg-holes from varnish, and file a set of pegs to fit. The bridge should be fitted to its position: between the V's of the sound-holes. No. 1 gouge will be about right for cutting the feet. The top of the bridge should have nearly the same curve as the finger-board, but should be about $\frac{3}{16}$ in. higher than the place at which a line along the top of the finger-board would terminate if extended to the bridge. The bridge will also need to be made a trifle thinner towards the top. Make four very shallow grooves with the file: these are for the strings to lay in. Fasten a piece of

Fig. 23.—Violin finished and strung.

strong gut into the tail-piece, of such length that when the loop is placed in the groove of the end pin the tail-piece is brought close to the bottom nut or rest.

*Setting Sound-Post, Stringing, and Screwing up.*—The sound-post should now be set in position; but, as remarked in the earlier part, there may be some difficulty in deciding which is the best place for it, and this can only be tested when the instrument is strung up. This can now be done. First, put the fourth or G string in the left-hand "slit" of the tail-piece, and through the peg nearest the finger-board; the first or E string is the next in order, then the third, and lastly the second string. Whilst the strings are quite slack, set the bridge in position, and screw the strings steadily up to pitch, alternately fourth and first, second and third, meanwhile observing that the bridge does not pull forward. Now, how do you like the tone? Of course everyone will remark, by way of encouragement, that "it is all right for a new fiddle," or "the tone is rather raw, but it will improve in two or three years." These observations are as certain as the stereotyped ones about the weather.

I do not know what other people may feel, but to me it was a moment of intense pleasure when I heard the first note from my first fiddle: exceeded, perhaps, when I heard the voice of double bass No. 1. This I was so anxious to do that it was strung up in the "white"—a mistake that will not occur again.

## SUBSTITUTE FOR HALL-STAND.

### EASILY AND CHEAPLY MADE.

BY B. R. CONDER.

AIM OF DESIGN—MATERIAL AND COST—HAT-STAND: DIMENSIONS AND CONSTRUCTION—DECORATION—MIRROR—DIMENSIONS AND CONSTRUCTION OF UMBRELLA-STAND AND CUPBOARD—TRAP-DOOR.

I PURPOSE describing briefly in the following paper two very easily and cheaply made, and yet thoroughly efficient, substitutes for a hall-stand. In planning them I aimed chiefly at economy of penee, and therefore of material, simplicity of construction, and consequent economy of time in making, and compactness. At the same time I was desirous to some extent that they should be ornamental, or, at least, not absolutely unsightly.

For the cheapness I ean answer, as the entire cost of material—wood, paint, brass hooks, and mirror—did not exceed 8s. They are made of deal, and painted with Aspinall's black enamel; as, however, so little wood is required, the cost would not be greatly inereased if, instead of deal, some ornamental wood, such as oak, mahogany, or walnut, were used.

The construction of the hat-stand, which we will consider first, is very simple, and a very short description of it will suffice.

Its dimensions are: extreme height, 2 ft. 6 in.; and width, 1 ft. 11½ in. It consists of an outer and an inner frame, which are mortised together. The four pieces forming the outer frame are 2½ in. wide and 1 in. thick, and their edges are stop-chamfered, as shown. The horizontal rails are mortised into the upright ones, 2½ in. from the ends of the latter, the tenons being carried about two-thirds of the way through. The parts of the inner frame

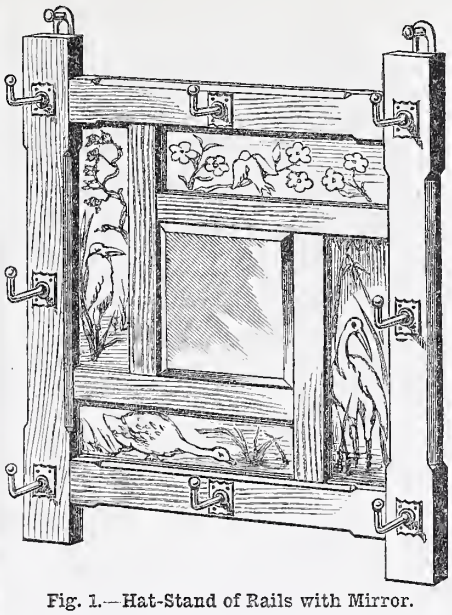

Fig. 1.—Hat-Stand of Rails with Mirror.

are 1½ in. wide, and only ¾ in. thick, so that, when fixed in place, their faces are flush with the inner chamfered edges of the outer frame, and both frames are flush at the back. They are mortised together and into the outer frame, in such a manner as to leave a space in the centre 9 in. high by 7½ in. broad for the glass, and oblong spaces 4 in. wide between each inner rail and the rail of the outer frame parallel with and nearest to it. A rebate of the required length is cut in each for the reception of the glass, which is secured at the back by a small beading. The whole framework is glued together, and if the tenons fit, as they should, so tightly into their respective mortises as to necessitate some little force being used to drive them home, nothing more is necessary. Care should be taken in joining up to keep it square. After this it is painted or otherwise decorated, the glass fixed in its place, and the hooks and plates by which to hang it to the wall screwed on, and it is complete. For purely decorative purposes I added a thin back, covered, where visible from the front, with Japanese gold leather paper, which improved its appearance wonderfully. The mirror might be dispensed with, and the centre space treated in the same manner. To those who intend using a mirror, I would suggest procuring it first, and making their framework, so to speak, to fit the glass; for the simple reason that one of stock size would cost considerably less than one made to order to a given measure.

The dimensions of the umbrella-stand are—length, 2 ft. 4½ in.; breadth, 9½ in.; and height to top of posts, 2 ft. 7½ in. Its construction is as follows: Four posts 1¼ in. square and 2 ft. 7½ in. long, whose edges are stop-chamfered, are connected by eight rails, which are mortised ¾ in. into them. These rails are ½ in. thick; the upper ones are 1½ in. wide, and are mortised into the posts 1½ in. below the tops of the latter; the lower ones are 3 in. wide, and their lower edges, which are rebated to take a thin bottom, are 1 in. above the floor. The front and back rails, top and bottom, are slightly notched at a distance of 7 in. from the posts, for the reception of the sides of the cupboard, which are let into them. These sides are of ½ in. stuff; they fall ¼ in. short of the under edges of the lower rails, to allow for the thickness of the bottom, and project the same distance above the top rails, in order to be let into the top of the cupboard, which is grooved to receive them. They are rebated to take a thin back, and grooved for the shelves, which are slid into their places from behind after the sides are fixed and before the back is screwed on. Their front edges are lined up to 1¼ in.

The various parts are glued together, with the exception of the bottom and the back of the cupboard, which are screwed on, the top being blocked inside for additional security.

Two large flower-pot saucers serve as receptacles for the drippings of wet umbrellas, though, doubtless, zinc trays would look better, and a small curtain answers the purpose of a cupboard door in screening from sight clothes-brushes, slippers, etc. Doubtless these little articles are more or less makeshifts; but they are extremely useful ones; and as their construction is so simple as to be within the ability of all who can use a saw, plane, and mortise-chisel with a very moderate degree of skill, and they can be made for about as many pence as a good hall-stand would cost shillings, they are by no means to be despised.

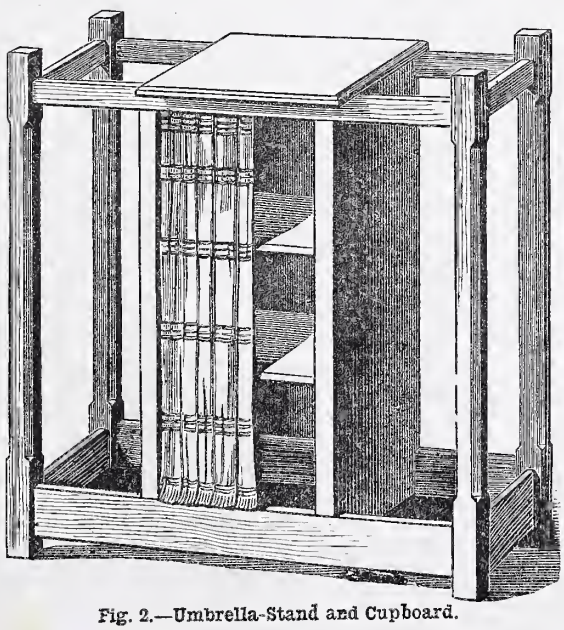

Fig. 2.—Umbrella-Stand and Cupboard.

## SOME WORDS TO WOULD-BE PATENTEES.

BY "AN INVENTOR."

WHERE TO FIND COPIES OF PATENTS—INDICES TO PATENTS—FORMS A AND A 2—POSTAGE—RULES FOR DRAWINGS—APPARATUS FOR COPYING DRAWINGS—COPYING MANUSCRIPT—CORRESPONDENCE WITH COMPTROLLER—REGISTRATION OF PATENT AGENTS—PROVISIONAL PROTECTION—WHEN ACTUAL PROTECTION COMMENCES—PROTECTION IN NEW ZEALAND.

"A CONSULTING ENGINEER" enforces the necessity of instituting "a most *careful* and *analytical* search through all the specifications *relating to the subject*," but omits to say where such search can be made, or how an inventor is to go about making the search; so I will supply the omission. In addition to the library at the Patent Office, full copies of every patent granted from March 11th, 1617, to the present time, with indices; reports of patent

trials, all carefully indexed, so as to enable anyone quickly to discover every question brought up in the Courts for decision; the official weekly journal, also carefully indexed, with abstracts, at the following places, which can be seen or copied by *anyone free of charge*:

Aberdeen, Public Library; Birmingham, Central Free Library; Bolton-le-Moors, Public Library, Exchange Buildings; Bradford (Yorks.), Free Library; Brighton, Free Library; Bristol, Free Library, King Street; Cardiff, Free Library and Museum, from 1871; Carlisle, Public Free Library, Police Office; Cork, Royal Cork Institution, Nelson Place; Derby, Free Library and Museum; Dublin, National Library of Ireland, Kildare Street; Glasgow, Stirling's Library, Millar Street; Halifax, Town Hall; Huddersfield, Corporation Offices; Hull, Mechanics' Institute, George Street; Ipswich, Museum Library, Museum Street; Keighley, Mechanics' Institute, North Street; Kidderminster, Free Library, Public Buildings, Vicar Street; Leeds, Public Library, Infirmary Buildings; Leicester, Free Library, Wellington Street; Liverpool, Free Library, William Brown Street; London, Patents Library, 25, Southampton Buildings, Chancery Lane, W.C.; ditto, British Museum; ditto, Free Library, London Street, Bethnal Green, from 1869; Manchester, Free Library, King Street; Newport (Mon.), Commercial Room. Town Hall; Nottingham, Free Public Libraries; Oldham, Free Library, Union Street; Plymouth, Free Library; Rochdale, Free Library, Town Hall; Salford, Free Library, Peel Park; Sheffield, Free Library, Surrey Street; Stockport, Central Free Library; Swansea, Free Library; Wolverhampton, Free Library.

If a private copy of any patent is desired, the price is marked on it in plain figures, and is sent free, plus the amount of postage (book rate), to any address in the country by the Comptroller of Patents, 25, Southampton Buildings, Chancery Lane, London, W.C. He will also send, post free, the Patents, etc., Act, 1883, for 1s. 9d.; ditto, 1885, 2d.; ditto, 1886, 2d.; ditto, 1888, 2d.; Patent Rules, 1883, 7d.; ditto, 1885, 3d.

The indices to the patents are chiefly of two kinds: viz., a *Name* Index and a *Subject Matter* Index; there are others also. This latter enables us to see at a glance the number of any patent for the year on the subject in hand, and the Patent Specification itself can be referred to at once on the shelves; and who so likely to recognise the same invention in another form as one who has invented or worked it out? Certainly he would be a very clever patent agent who could equal all-round, on every subject, every inventor; but if a visit is paid in the daytime, we shall find youths—merely lads—doing the searching for local patent agents. Everything is so nicely arranged, that as soon as the system is understood, the back patents on the subject can all be quickly examined: this *may* be done before applying for a patent, but I should never advise an inventor to employ a professional patent agent, as, if he is capable of inventing anything, he is quite qualified to "search." Reports of ALL patent cases tried in the Courts are also SUBJECT MATTER indexed, so that easy reference can be made to any subject tested; in fact, carefully reading and studying these reports will give inventors more insight into the requirements of the Patent Laws, and how to understand the various Acts of Parliament, than all the patent agents' circulars and barristers' law books—written for ignorant inventors—put together. When a man can be his own lawyer, he has an advocate that will do his utmost for his clients' interests, and such a one will not always keep an eye on future possible employment. The greatest crime a professional man can do, whether a patent agent or solicitor, is doing things "unprofessionally"—that is, depriving himself and his professional brethren of all chance of making a *future* "picking." This is no advantage to a patentee, therefore he should learn to do things himself, so as to be able to tell if they are done right, even if he does not do them himself.

This article should be read as a supplement to that of "C. C. C." in WORK, Vol. I., page 545, in which all statements may be considered as being fairly correct, with the exception of the following:—Form A is the Application Form when applying for a patent by an original inventor or a British invention; Form A 1 is used when the invention is an imported foreign one, taken out in the name of a resident in this country; Form A 2 is for use when a foreign inventor applies in his own name, but wants it dating back to correspond with the date of his home foreign patent.

There is no need to pay postage on any package sent to Patent Office, beyond the stamps on the forms; just write on, "O. H. M. S.," this is quite enough; so that if the inventor does the work himself, the cost out of pocket to get his patent is just £4—no less or more.

The rules for the drawings are not on the form for the "Complete" Specification; the requirements are, that it be *white drawing* paper—Windsor and Newton's keep it, and it can be had from their customers; most drawing papers have a "creamy" colour, which is objected to; the "white" is often difficult to get. The size to cut it is 13 in. by 8 in., or 13 in. by 16 in., and must have a margin drawn half an inch from the edge all round, within which all the writing and drawing is to be done. If the drawings are done to scale, the scale must also be shown on every sheet; on the top right-hand corner of each sheet, must be marked the number of sheets of drawings, and what number that sheet is; on the left-hand top corner is to be marked the number and year, and whose Specification it is; on the bottom right-hand corner the sheet has to be signed by the applicant or his agent, and every drawing must be in duplicate, one of which must be marked a "True Copy."

Now, to most people it is no joke to make a drawing on thick drawing paper in Indian ink, and then make a *true copy* of it, exact in every respect. It was a difficulty I was much puzzled over at first; but, however, I hit on a plan at once simple and efficient, which I think will be found of use to many more people besides what are likely to take out patents; for instance, I showed the plan to a lithographic printer, and he was delighted with it as a means of taking tracings on "transfer-paper," to lay down on the stone.

The whole apparatus is the most simple and inexpensive, and the materials may be found in every house, and fixed up in a few minutes—in fact, I had my first working in half an hour. Fig. 1 shows at A a common box—it does not matter whether it is square or oblong—with one side and the top removed; C is a sheet of common looking-glass; if one is not found in the house—which is very unlikely—it can be had of any small ware dealer for sixpence: this is fixed at an angle of 45 degrees, which is to reflect the light *upwards* from the gas or lamp, Fig. 2. No tools are required to do this correctly: just light the gas or lamp, and look *downwards* until you see the light fairly in the centre of the glass, then drive two tacks in the box, at the foot of the looking-glass, to keep it from slipping out of place; the looking-glass can thus be fixed into the box, and taken out any time. A plain level sheet of transparent glass is now fixed on the top to trace on, when the box is complete. Fig. 2 shows a gas burner, but I prefer to use a petroleum lamp, with another looking-glass on one side to reflect more light into the box, and an opaque shade fixed on the chimney to keep the light out of the eyes while working.

Fig. 3 is a spring clip, to clip the two sheets together while being copied; two of them will be required for opposite diagonal corners: these are made out of a piece of clock spring or other similar sheet steel. I make them by holding a piece in the gas till hot, and then bending the two ends close together. I first of all make a drawing on thin white paper, on a drawing-board, which is finished in ink as black as possible; this will perhaps have numerous compass holes in it. When I have got it right I fix it under a sheet of drawing paper by means of the clips, Fig. 3; and now lay it on the sheet of glass B, on top of A, when the reflected light from lamp, or gas, will show clear through, making the drawing quite distinct, which I can quickly trace in Indian ink; the two sheets being clipped together enables me to turn them about anyhow so as to fix it just right for drawing every line. I can thus make any number of exact copies on the thickest drawing paper.

I am not sure that this plan of making exact copies is new or not. I have never seen it described, and it is, as far as I am concerned, my own invention: which, though it may be largely used, is really one of those things that are not worth patenting, simply because everyone who wanted to use one would make his own, and there could be no means of detecting him, or getting in any royalties.

The Tracing Box will meet a great want, both amongst amateur and professional patent agents, as very few can copy their own drawings satisfactorily.

There is no limit to the number of sheets, either in Drawings or Specifications, that may be sent in, and here again I may give another useful wrinkle. All documents require to be in duplicate, and fifty or more sheets of foolscap manuscript is no joke to copy. I work it thus: the rules say "written or printed," so I write the Specification in strong copying ink; I then get some strong thin sheets of unruled white foolscap paper, and place a wet cotton cloth between two sheets until quite damp, and then copy on these in the press in the ordinary way, taking *two* copies, one to keep and one for the Patent Office, to go with the original; the ink strikes through, and shows well on the other side. These copied duplicate sheets are quite within the rules, and are really preferred at the Patent Office, as only one set need be examined.

Having said thus much, I will now tell the public what treatment they may expect from the officials at the Patent Office. This is it: if you want any information regarding taking out a patent, write a courteous and respectful letter to the Comptroller—no need to pay postage—and he will send you a courteous reply back, giving, if possible, the information you ask for *all for nothing*—in

fact, I need to say no more than "Write for particulars to the Comptroller." Patent Agents think he interferes with their business by doing this, though he is strictly doing his duty to the public, as one of their servants. I will try to make it clear why this is so. The Patent Laws and the Patent Office exist for the benefit of the *public*, not for Inventors, nor yet for Patent Agents. Every useful invention is a public gain, and the duty of the Comptroller is to collect, and make public, every invention he possibly can, so that the public may have the benefit of it; the offer of a patent for a term of years, on behalf of the Crown, is an inducement he is allowed by Parliament to offer to all inventors who disclose their inventions to him: he naturally wishes to induce as many inventors as possible to come forward, and he certainly would not be doing this by giving them *worthless* patents; he therefore, to inspire trust and confidence amongst inventors, carefully examines all Specifications sent in, and if he notes any fault or error, he sends it back to be rectified. I have seen Specifications sent back because a comma had been omitted. It certainly is not his fault, if a Specification is defectively drawn; what he does, and has done, and what I have heard patentees say in the Local Patent Library he has done for them, in the way of help, seems too absurd to relate. The Yankee tale about the railroad agent (station-master) who kept a train waiting until an old hen laid an egg, to oblige a woman who was one short of a dozen to send by it, quite pales before the stories I have heard.

If you go to a Tax Office, you may be treated with scant ceremony, because *you are obliged to go*. But not so at the Patent Office: there the whole British public employs the Comptroller and his staff, to get your invention out of you, for *their* benefit, not yours; so it is his duty to use every inducement the law allows him to get it. Professional Patent Agents may want to stand between the inventor and the Patent Office, but there is very little need for their services, and inventors should look out for themselves, or their rights will be seriously curtailed. Patent Agents got the thin end of the wedge in by the Act of 1888; they will not be long before they give another blow to the freedom of inventors. So far, there is nothing to prevent "C. C. C." or anyone else acting as an "unauthorised" Patent Agent, or offering his *services* or assistance to inventors by advertisement, as long as he does not call himself "Patent Agent," or sign the documents as "Agent." As long as everything is done in the *name of the Inventor*, and all the signing is done *by him*, it does not matter who draws the documents up. I see Patent Agents are advertising themselves as "Registered," implying that they are "duly qualified." The Act of 1888 says: no person shall represent himself as a "Patent Agent' unless he is registered; but on the other hand, any person who has acted as a Patent Agent previous to the passing of the Act *is entitled to be registered*, no matter how little his knowledge of Patent matters may be. In future, the principal condition on which Patent Agents may be registered, is that they have served for a certain time to one of these possibly incompetent registered agents; thus the public get no guarantee. In fact, the Act of 1888 is simply to keep down the supply of Patent Agents, because many were doing work, under trade-statement prices. I have no sympathy with anyone who wishes to dictate or regulate the price of anything. I hold that the Law of Supply and Demand should do this; nor do I hold that anyone has a right to dictate to another man how little or how much he shall demand for his skill or labour. If a man wants a good price for his work, let him excel everyone else in its *quality*, and sooner or later he will get all he asks, no matter how others may be cutting under him. Many Patent Agents quote "so much" for taking out a patent, which they do on the principle of "averages"—that is, taking one with another. If a man chooses to do his business in this manner, he has a perfect right to do so, and I am not going to blame him, nor hint that such a person's work is not to be depended on; on the contrary, some of the Patent Agents who do business in this way are the most competent, trustworthy, and reliable in the profession.

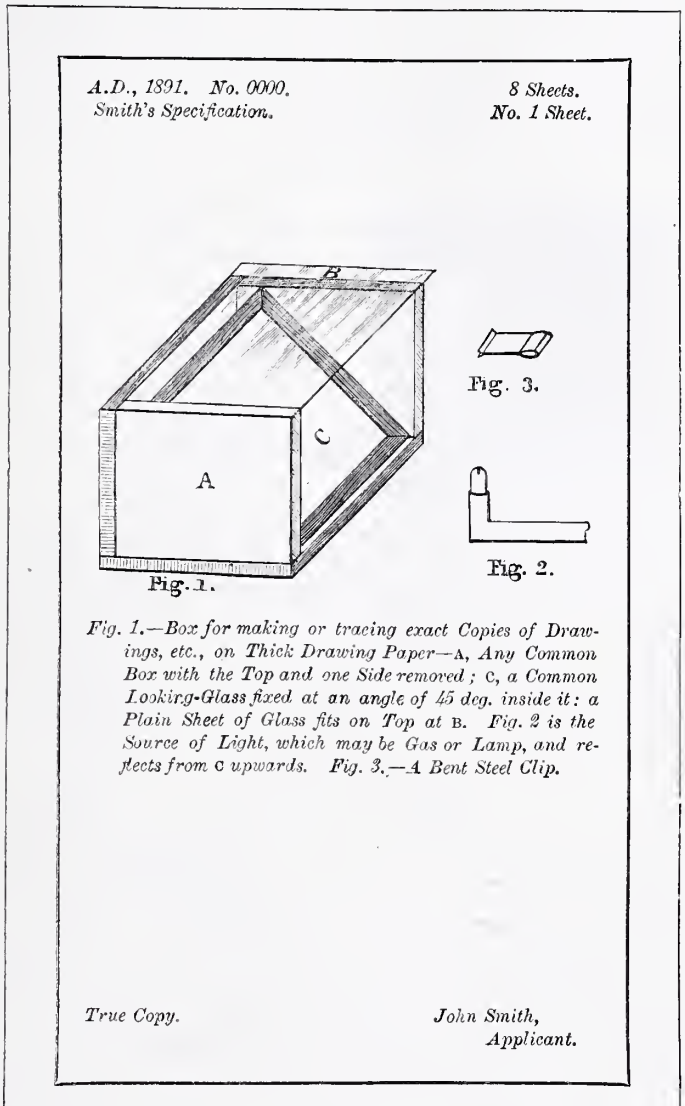

*Fig. 1.—Box for making or tracing exact Copies of Drawings, etc., on Thick Drawing Paper—*A, *Any Common Box with the Top and one Side removed;* C, *a Common Looking-Glass fixed at an angle of 45 deg. inside it: a Plain Sheet of Glass fits on Top at* B. *Fig. 2 is the Source of Light, which may be Gas or Lamp, and reflects from* C *upwards. Fig. 3.—A Bent Steel Clip.*

**Example of Sheet of Drawings for Patent Office.**

In No. 46, page 731, "C. C. C." does not draw quite safe deductions. I agree with him that "Provisional Protection" makes an inventor "as safe as if the patent had actually been granted"; but it gives him no protection against anyone who infringes *previous to the date of the acceptance of the Complete Specification*. If the infringer is a sharp, unscrupulous person, he might assert that he had been publicly making and selling the things *previous* to the date of the patent; and as such statement is not on oath, no charge of perjury can be made; no doubt he will have confederates to whom he will kindly refer you, who will show you invoices dated months previously, so a timid inventor may be frightened out of his rights; such a person, by lodging the proper form at the Patent Office (price 5s.), will be duly informed of every step taken; so that as soon as the Complete Specification is accepted, he can either back out scot free, or file opposition; if he does this, he may get a perpetual free licence to "square" him. This is no imaginary matter. In one patent I took out, I simply said that I had solved a problem that had been before the world ten years for anyone to solve. The matter was noised all through the trade; everyone was soon guessing, and numberless were the tricks resorted to, to learn how the thing was done; but kind friends told me to be cautious, because no matter what it was, it was decided to declare that it was "old."

One party professed to be my friend, and begged me to tell, just himself, as a particular favour, and he would be strictly "masonic" over it. I would not until after the date of acceptance of Complete Specification, though I made no secret of what the thing was like, and invited anyone to guess; one editor said if I could do that, it would be a novelty indeed. As soon as it was known what it was, up they all jumped to cry that it was *old*, my particular "masonic" friend heading the lot; and though they were twelve months after the date of my patent, and though I hold letters, in which it is declared such a thing is absolutely impossible, and hinting that I was surely taking them in, they actually presented me with a very formidable-looking list of names of people, who they said had made and used such, previous to the date of my patent. What inventors should do, is to always file a Provisional Specification, and delay filing the Complete one as long as possible, keeping their invention as secret as possible in the meantime; by this means, they get ten or twelve months' start of all such gentlemen.

"Patentee," page 574, No. 36, must read

Acts of Parliament differently if he is to teach Law. Patent Specifications are always interpreted according to what they *mean*; whilst Acts of Parliament are interpreted by what they *say*. Let him read section 14 again: he will see that it simply says that an invention for which a patent has been applied for, may be used and published, without prejudice to the *grant of a patent;* section 15 invests him with all the rights and privileges of a patentee from the date of the acceptance of the *Complete* Specification, though he does not get his patent for ten weeks after. If Parliament had intended a patentee to have the privileges of a patentee from the date of his patent, or the date of Provisional Specification, they would have said so; but instead, the Act says clearly and distinctly "the date of the acceptance of the *Complete* Specification." *Therefore it is, or should be, clearly evident to anyone of ordinary comprehension* —unless it is "Patentee"—that no action can be brought on anything done in infringement previous to the date of the acceptance of the Complete Specification, simply because Parliament says a patentee shall not go beyond that date in claiming anything in an action for infringement; while section 13 says, "Every patent shall be dated and sealed as of the day of the application, provided that no proceedings shall be taken in respect of an infringement committed before the publication of the Complete Specification."

On the 1st of January, 1890, a new Act came in force in New Zealand, entitled a "Patents, Designs, and Trade Marks Act"; it is almost word for word, the British Act of 1883, the forms being obtainable at any money-order office in the colony, and transmissible by post. The principal differences are as follows: 10s. is payable in filing application, which may be accompanied with a Provisional or Complete Specification; 10s. on filing a Complete Specification in nine months, and £2 on sealing the patent: total fees, £3. There is a further payment of £5 before the fourth year, and £10 the seventh year; but there is a new departure, that I think all inventors will be interested in, *viz.*, that British patentees have twelve months from the date of their British patents to apply in New Zealand for a patent, and when they do apply, the patent takes the same date as the British one, so that all British patentees get twelve months' Provisional protection in the colony.

There are quite a number of matters I have left untouched; but should any difficulty arise, they can be answered in "Shop." The present paper will, along with "C. C. C.'s" article, act as a good guide, and what is not mentioned will, I think, be readily found in the libraries I have given a list of. Thousands of inventors daily pass them in ignorance of their existence, or that they have a perfect right of access to everything in them *free of any charge whatever*, no matter where they live or come from. It is only right that information on this point should be placed within the knowledge of the readers of WORK, and this I have sought to supply to the best of my power in the foregoing remarks on this subject.

## A HANDY MEAT SAFE.

BY "AN AMATEUR CARPENTER."

INTRODUCTION—WOOD—CONSTRUCTION OF PARTS AND PUTTING TOGETHER—CONCLUSION.

*Introduction.*—Now that the hot weather is coming on—or, at least, summer is approaching—a meat safe will be a very useful article in which to store commodities of daily consumption in the household, and all things that are likely to suffer from the delicate attentions of the inquisitive housefly. It is especially hard in hot weather to keep articles from going bad, and, besides, a safe is a very simple article to make, so that the amateur may not shrink from attempting to construct such a useful thing, as anyone with a slight knowledge of carpentry and a few simple tools can do so.

I will now proceed and give some instructions to help in making one.

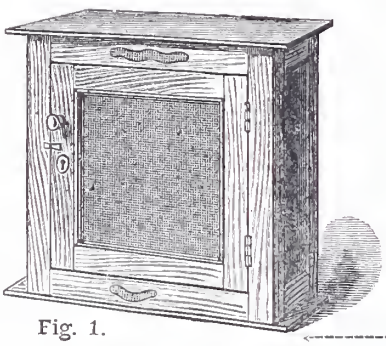

Fig. 1.

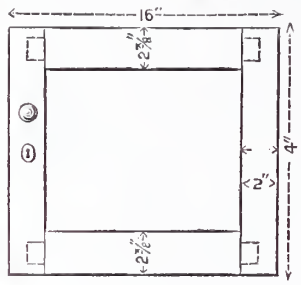

Fig. 2.

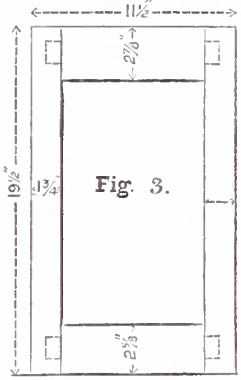

Fig. 3.

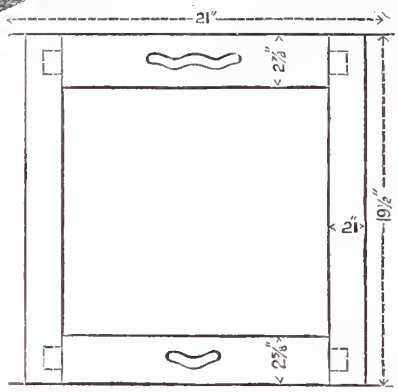

Fig. 4.

Fig. 1.—Safe complete, in perspective. Fig. 2.—Framing of Door. Fig. 3.—Side of Safe. Fig. 4.—Framing of Front in which Door (Fig. 2) is hung.

*Wood.*—The best wood will be yellow pine, and the sizes that are wanted can be seen by referring to the illustrations. It had better be about ½ in. or ⅝ in. thick.

*Construction of Parts.*—Fig. 1 shows the safe complete, in perspective. Fig. 2 is a view of the door. About 14 in. high by 16 in. wide would be a good size for the outside measurements. The width of the wood for the top and bottom pieces had better be about 2¾ in., and the uprights about 2 in. across. Fig. 3 shows the side piece, two of which must be made. The sizes and length of the wood are shown in the illustrations. In this figure, and also in Figs. 2 and 4, the joints had better be mortised and tenoned if the reader cares to. Fig. 4 shows the arrangement minus the door. The two holes cut in the top and bottom are for the zinc to be nailed at the back of each. Of course, it is understood that zinc will be wanted for the door and side pieces. In Fig. 3, it will be noticed that there is another line on one side of one of the uprights. This is to show how the front is joined, and that line represents the thickness of the wood of Fig. 4, and the way of putting together. For the top and bottom and back of the safe, some small planks of wood must be nailed on to the uprights. The interior had better be fitted with a shelf and a small hook, attached to the top of the safe, for hanging meat on. The shelf, for convenience, may be made so as to be removed in case it is wanted, as a large joint of meat would not be able to hang unless the shelf was very low, which would not do, as nothing could be placed underneath it.

*Conclusion.*—In concluding, I may say that I think the reader would find it very easy to put the parts together, and also to make them. The boards at the top and bottom had better be about ½ in. each way wider than the uprights; and if it be exposed to the damp or rain, some thick felt (which can be got at most ironmongers' at about 6d. per yard) had better be nailed on the top. The other fittings, viz., a pair of hinges, a lock and key, and a small handle, can be obtained at almost any local ironmonger's, as can also the zinc which will be wanted for the door and sides. Any inquiries on points not made quite clear I shall be happy to answer through the medium of "Shop."

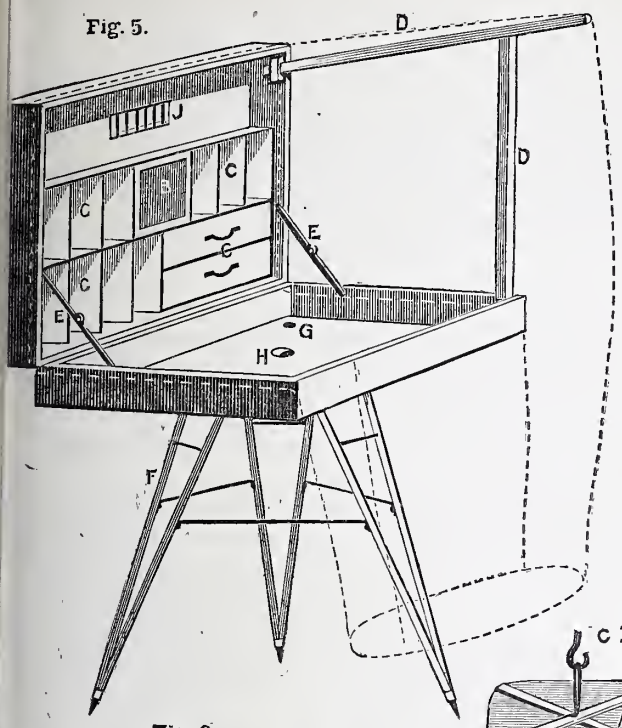
## PHOTOGRAPHIC TENTS.

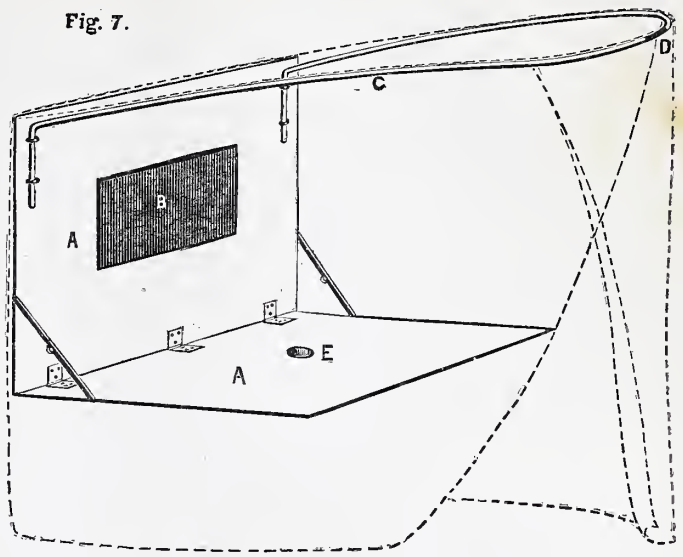
BY AN OLD HAND.

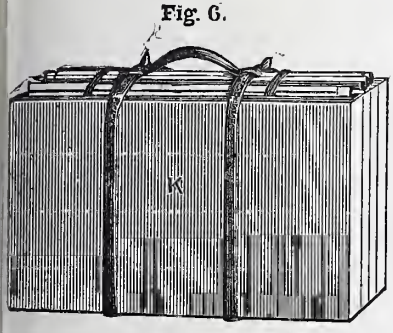
TRAVELLING TENT—FOLDING TENT—HOWARD TENT—PLATE CHANGING BOX—LIGHT CHANGING BOX—SACK TENT.

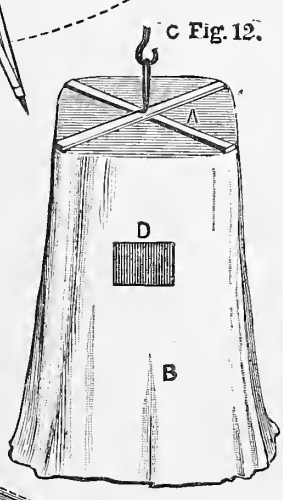
No. 2 is a lighter and more portable form of tent, useful when the smaller sizes of plate have to be developed; but as the room inside is somewhat limited, the face is necessarily much over the developer, and if ammonia is used, is somewhat disagreeable to work in, besides being close and hot. It is, however, a practicable tent enough for occasional use, for merely changing plates and ticketing them is all that is necessary. It consists of two shallow double boxes hinged together, each 24 in. by 16 in., and 2 in. deep. When open, the half that is raised up, and kept in place by a knee and strut on each side, is partitioned out for holding bottles, brushes, etc., with a small ruby glass window in the middle. The lower half is screwed on to a stout tripod, and acts as a receptacle for the frame and cover when packed, and which is not removable, as in No. 1, but carefully attached to the case in the manner shown in the diagram. It is intended that the operator shall stand to work in this tent. He slips the bag at the back over his head, and fastens it round his waist with a buckle and strap, the upper part of his body only being under cover. The fixing bath is arranged as in No. 1, the water supply being contained in an indiarubber bottle hanging outside the tent, and communicating by means of an indiarubber tube with the inside, where it terminates with a pinch tap. The ventilator is similar to No. 1.

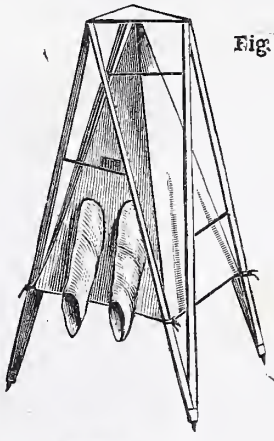
No. 3 is somewhat similar in design, but, instead of the double box, consists of two boards arranged in a similar fashion, and fixed in position with elbow struts, with a window in the upright one. The framework

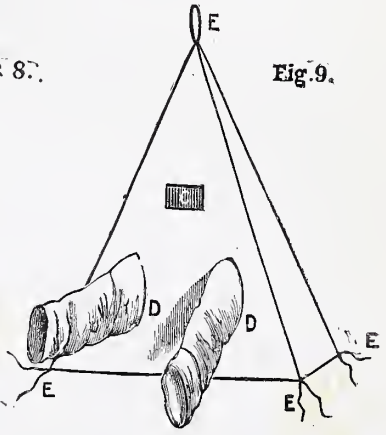


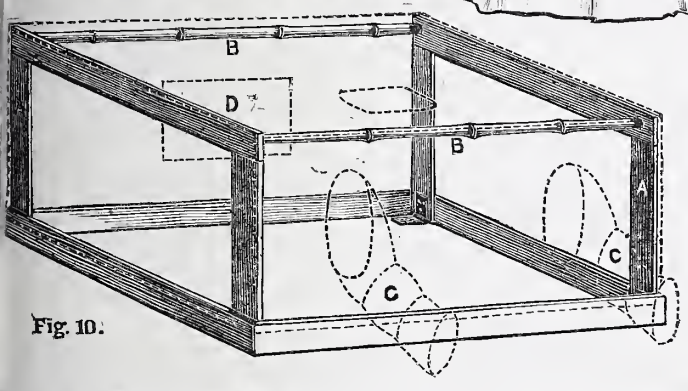


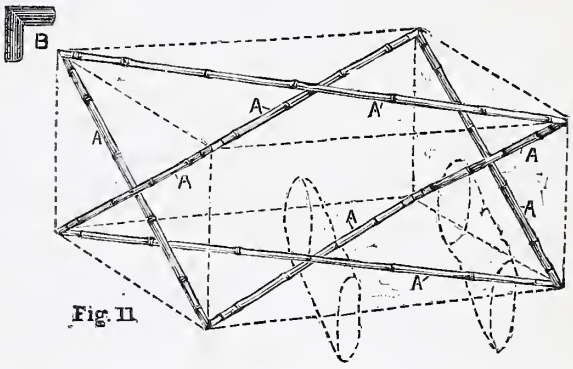












ENT No. 2. Fig. 5.—Tent Set up—B, Ruby Window; C, Partitions for Bottles; D, Framework of One Side; E, Strut; F, Tripod; G, Hole for Waste Pipe; H, Bolt to Tripod; J, Ventilator. Dotted Lines show where Covering is attached to Woodwork and Bag Entrance. Fig. 6.—Tent packed, with Tripod at top for transit. TENT No. 3. Fig. 7.—Bottom and Front of Tent—B, Window; C, Iron Wire to support Covering, hinged at D; E, Screw Hole to attach to Tripod. Dotted Lines indicate Cover. TENT No. 4.—THE HOWARD TENT. Fig. 8.—Triangular Bag suspended under Tripod Head. Fig. 9.—Bag detached—C, Ruby Window; D, Sleeves; E, Cords to attach to Tripod Head. TENT No. 5. Fig. 10.—Tent showing Details—A, Frames of quarter-inch Mahogany hinged to each End of Box and folding down when not in Use; B, Bamboo Rods sprung into Hollows in the Frames to stretch out the Covering and support the Ends; C, Sleeves; D, Window. Dotted Lines show where Cover is attached to Tray. To pack, remove Stretchers, and fold down the End Frames and Cover into Tray; put a Strap round to carry it with, and the whole is complete. TENT No. 6. Fig. 11.—A, Bamboo Rods, each Pair pivoted in Centre; B, L-Shaped Ferrule. TENT No. 7.—SACK TENT. Fig. 12.—Tent set up—A, Wood Cross-Pieces; B, Sack; C, Hook in Ceiling; D, Window.

onsists of two uprights screwed to the ack edge of the lower board, and folding arallel with it when out of use. To fix or use, they are placed upright, and a iece of iron wire jointed in the centre f the back overhead—the opposite ends eing bent at right angles—is fitted into yes attached to the front board. In his case the cover is detachable, and made of one thickness of ruby and one of black twill, similar in make to the cover of No. 1, an opening being cut in the front to admit light, and cross-folded at the back, folding a few inches under the bottom board, and retained in place by a cord. A band with hook and eye fastens round the operator's waist. This tent is only suitable for changing plates and marking them. Of course, it might be used for development in an emergency. The cover is removed, the wire frame doubled, the boards shut together, and the cover wrapped round them and strapped up for carriage.

No. 4 is called a Howard tent, from the name of its designer. It consists of a triangular bag of three thicknesses of material, and is suspended under the tripod

head, the window being made by removing the outer thickness, leaving the yellow and red. The lower corners of the triangle are tied by tapes to the legs of the tripod, which is opened a definite width, and kept so by struts. A small ruby glass window is let in on the one side, also two sleeves, one of them of sufficient width to admit the dark slides and plates, and about 8 in. long, with elastic bands a few inches apart to prevent the light entering when the hands are inserted. The operator looks through the ruby glass, and can easily change his plates. Of course, this tent is unsuitable for the development of gelatine plates, although, by having a folding board for the bottom and a rubber drainage pipe, small plates could be worked in it. The size of the tent is determined by its height from the ground and the width of the legs apart.

No 5 is a tent in which the hands of the operator only are inside; it is thus made. A tray of any desired area, with a frame hinged at each end, which, when not in use, folds on the bottom of the tray. To fix, turn the frames upright, and secure with struts. The cover is attached to the tray, and strained tightly by the upright frames. A window is left on one side, and a ruby glass eye-piece, so to say, on the other; two sleeves, with elastics, allow the manipulation of the plates. In packing, fold down frames and covering, and strap up.

No. 6 is, perhaps, the very lightest contrivance made for changing plates. It consists of eight bamboo rods, each long pair pivoted together in the centre, the shorter ones forming the ends, the longer ones the top and bottom. The end ones are provided with L-ferrules, and the whole covered with an oblong bag, made of a size that will be tightened out when the bamboo rods are opened and fixed. This is provided with two sleeves, as the others. The changing of the plates is entirely done by feel—an easy enough plan after a little practice. A small gummed label fixed on the back of the plates will facilitate matters. The bag may be made of one thickness of black velvet and one of ruby cloth. When packed, the whole makes but a small bundle, and cannot get out of order. Of course, in all these tent-coverings the sewing must be carefully done, and carefully examined afterwards to ascertain its perfectly light-tight condition; inside any wood or metal work blackened with black varnish, to minimise chance reflections.

No. 7 is called a sack tent. It consists of a cylinder of red and black twill, of any suitable diameter, the closed end supported by a cross-piece of wood, two strips pivoted in the centre, with a pin to keep them in place. These are placed at the closed end of the sack, which should be made square, and suspended to a hook in the ceiling of the room. The length of the bag is such that when the operator is inside there will be a few inches space above his head, and two or three inches in folds upon the floor. A window is left by cutting away a few inches of space in the black cover. This, of course, is only intended for changing plates of small size, which may be carried in a satchel hung over the shoulders. Three or four carpet pins will, by pinning the lower edges to the floor, prevent it being accidentally lifted during the exposure of the plates. All tents for photographic operations must be light-tight, with plenty of air-space and elbow-room, easily set up and taken down, and with as few loose pieces as possible.

## OUR GUIDE TO GOOD THINGS.

**** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 34.—The Patent Ball-Bearing Castor.

The Patent Ball-Bearing Castor Company, Highfield Works, Upper Kent Street, Leicester, send me the following letter:—"A gentleman so far away as Leith, N.B., has called our attention to your notice in issue of the 2nd inst. of a castor. He is of opinion that our castor is far superior, and we need hardly say that we think so too. However, we submit a set for your inspection, with one not closed up that you may judge; and we trust that it may so far meet with your approval as to deserve and receive a notice." The appearance of this castor is decidedly attractive, being on a central vertical bearing, as may be seen from Fig. 1, in which

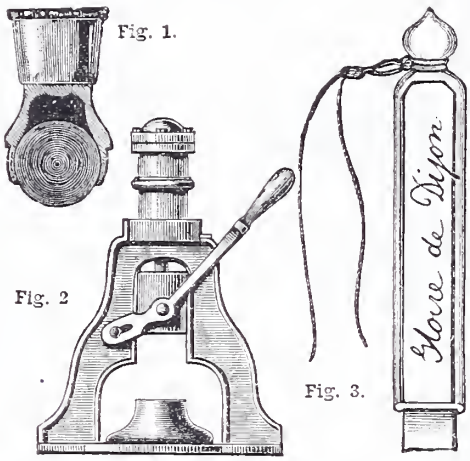


**Fig. 1.—Patent Ball-Bearing Castor. Fig. 2.—Doughty's Nut-Cracker. Fig. 3.—Gilles' Crystal Waterproof Garden Label.**

the cup that is closed on and over the ball that forms the castor is shown in section. The castor is made in two parts, an upper socket furnished with three or four screw-holes, as the case may be, which is fitted into and braced to the lower cup, which is inverted and closed over the ball on which the table or other article of furniture to which these castors may be attached is moved. Between the ball and top of the cup five small balls are placed, but these are not shown in Fig. 1. When all the balls are in position, the edge of the cup is closed in on the large ball sufficiently to prevent it from falling out, but not so tightly as to deprive it of free revolution in any direction. Now, in theory the castor seems everything that can be desired, and, as far as appearance goes, it is the most attractive form of castor that I have ever seen. I am, however, prevented from trying the effect on a heavy table, as there are only three in the set sent, whereas the table with which I should otherwise have tested them is a quadruped, having four legs. In working them with the hand, under both light and heavy pressure, I find, as I expected, that there is a tendency to jam, and then the large ball is drawn or dragged, without revolution, along the surface over which it is passing, and I am afraid that this tendency would become even more pronounced when the castors are attached to a heavy table or piece of furniture. The Company are right, I think, in describing them as "practically impossible to break or get out of order" (jamming excepted); and in saying that their "use imparts a certain finish and elegance, thus commending themselves to every lover of artistic effect, and entirely superseding the crank and wheel castor of the old type." These castors are made in brass, burnished, lacquered, and highly finished, fitted with metal or vitrified glazed spherical rollers and polished steel bearings, and are supplied in various sizes and patterns—namely, socket plain, socket scalloped; plate, with three screw-holes or central wood screw, or both combined: cabriole; with plate, special pattern, for pianos; and for iron and brass bedsteads, etc. They are also made in suitable forms for heavy window sashes, to facilitate opening or closing, sliding doors or partitions, portable baths, and heavy travelling trunks, etc. They are supplied in eleven sizes, ranging from ⅞ in. to 2½ in. inside measurement, and the price ranges from 2s. 6d. to 12s. per set of four. Further information will doubtless be accorded by the Company to anyone who may apply for it.

### 35.—Doughty's Nut-Cracker.

The form and construction of this nut-cracker, from the registered design of Mr. George Doughty, Allnutt Estate, Epping, Essex, will be readily understood from the illustration that is given of it in Fig. 2. As will be noted by those who are familiar with these machines, it is in the shape of a steam hammer. The main casting consists of a base-plate, from which spring the standards on each side, united at the top to support the central tube, whose top is closed over by a plate of the same diameter, secured by four screws, which pass through the plate and the flange encircling the top of the tube. The hammer or crusher is grooved on each side to permit it to work up and down the inner sides of the standards. It is actuated by a lever fastened to the hammer by a pin, about which it works freely, and to the left-hand standard by another pin, which passes through a slot in the fixed end sufficiently long to enable it to move along the pin, when the handle at the upper end is depressed. In the centre of the plate at the base is an "anvil," if I may call it so, attached by a screw, and grooved crosswise at the top to retain any nut that is placed on it in a proper position for cracking. To use the appliance, you place the nut on the anvil, place the *palm* of the right hand on the handle, and apply pressure, not as a blow, but as pressure. On removing the hand from the lever, the hammer moves up to its previous position, being raised by a spring hidden from view in the tube at the top, leaving the nut cracked on the anvil. It will crack nuts of any size, from a Spanish nut to a walnut or a Brazil nut. It is certainly safer and surer in its operation than the old-fashioned nut-cracker. Mr. Doughty tells me that he will send one to any address for 2s. 6d., post free. The iron casting is painted red, or rather vermilion, and it is gilt in the prominent parts, so that it presents an ornamental appearance.

### 36.—Gilles' Crystal Waterproof Garden Label.

In this I have something good for gardeners, who are often perplexed by the untoward condition to which their labels are reduced, when painted and written on with a pencil, by the combined influences of rain and dirt. In the Crystal Waterproof Garden Label, Mr. W. C. Gilles, 172, Portland Road, South Norwood, London, S.E., has provided a boon for all gardeners, professional and amateur, which, it is to be hoped, will be appreciated by them as it should be. The contrivance is illustrated in Fig. 3. It consists of a flattened tube of glass with a knob at the top, which renders it highly convenient for attaching it to trees, shrubs, plants, or garden sticks, by string in the manner shown in the illustration. At the lower end it is open to receive a slip of Willesden paper, doubled, on which the name of the tree, etc., to which it is attached, is written. The weight of the glass keeps the label in a pendant position, so that no rain can find its way into the inside of the tube to injure the label, and the writing on the paper must then remain

ible for any length of time. For labelling es it is most desirable, and, I believe, it has en taken into use by numerous firms who make se culture a speciality. When the durability d legibility of the inscription within are taken o account, the prices for the two sizes in hich the labels are made are most reasonable, e smaller size being supplied at 1s. 6d. per zen. Both sizes are sent post free for 2d. per zen extra. Visitors to the Crystal Palace, denham, may see them in use in the grounds.

THE EDITOR.

### CORNER FOR THOSE WHO WANT TO TALK IT.

*In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—LETTERS FROM CORRESPONDENTS.

**Photo-Lithography.**—A. J. A. (*Holborn, E.C.*) rites:—"In reference to PEN AND INK (see WORK, o. 113, page 142) requiring information regarding thography or zincography, I must presume he is n entire novice, and does not know anything about thography, or he would surely mention whether e requires information in the artistic or printing epartment, these being two distinct branches of ie same trade. So starting with this idea, and for eneral information, it may be interesting to note iat lithography is a means of bringing before the ublic in a cheap form copies of notable pictures, hich it would be otherwise impossible for them to btain, besides bringing the public taste to a higher vel as regarded from an artistic point of view. I o not speak about those wretched posters one sees n every hoarding, but to those charming pictures y well-known artists which one may see any day ecorating the home walls. Take, for example, the hristmas and summer numbers to nearly every aper, which are all now beautifully illustrated by ieans of this interesting art. Then, again, our Christ- ias cards, which I do not believe nine people out of n give a thought to *how* is it done, but which think one and all agree in saying 'How pretty!' But o turn to the practical part of the business. Suposing PEN AND INK wishes to become a lithoraphic printer, he would serve an apprenticeship or five or seven years, paying a premium which aries in different firms, when he would learn verything appertaining to the lithographic printer, xcept drawing on the stone. But should he wish o become a lithographic draughtsman or artist, he ould still have to serve his apprenticeship, though i another department. Should he have sufficient nergy and patience to study at home, I trust the ew hints given in Nos. 106, 109, and 112 of WORK, ith those to follow on this subject, will be of some ight assistance in enabling the noviee to overcome he difficulties of beginning a new study. With espect to zincography, the only difference between hat and lithography is that the latter is drawing n stone, and in the former one draws upon zinc lates, of which there are two kinds—the grey oned ones with which we are all familiar, and ately Messrs. Vincent, Brooks, Day & Sons have ntroduced into the trade a zinc plate with a litho oating, which certainly makes them more pleasant o work upon, being so mueh nearer stone colour; ut in both lithography and zincography the mode f proceeding is precisely similar, regarding it from he artist's point of view. But if PEN AND INK will sk definitely what it is he requires to know, I hall be pleased, with the Editor's approval, to nswer any questions, as I am afraid I have already neroached too much on his valuable space."

**"Work" Exhibition Testimonial.**—F. W. T. *Heathfield*) writes:—"I beg here to enclose my incere thanks for the splendid Book Prize and ertificate, which have arrived quite safely. I am orry I could not attend the Distribution of Prizes, s I should very much have liked to have been at he close of what has been, not only a great interest o me, but has evidently established me in the conidence of the public, which nothing else in my osition could have done. I have here to express my ratitude to Messrs. Cassell & Co., and our worthy ditor of WORK, who first established in me the reat object of bringing the mind into more studies han one. I therefore hope that such a valuable olume as WORK may still double its present xtensive circulation, and be of as much service to thers as it has been to me."

### II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**Optical Lantern Condensers and Objectives.**—F. J. D. (*Stoke Newington*) has constructed a agic lantern, and fitted the same with a single ondenser and objective, but is desirous of re-fitting it with better lenses, as the result is by no means satisfactory. The indistinctness of the single condenser is caused by the loss of light attendant upon the necessarily long focus of the lens. For example, a 4 in. condenser of, say, 6 in. focus will receive only about a fourth of the light it would if it were half this focus; but, on the other hand, shortening the focus of the lens would mean a considerable increase in its thickness, and consequently a greater liability to fracture, owing to the necessity of placing it nearer to the source of light; hence the advantage of using a compound condenser, in which a couple of lenses of, say, 6 in. focal length can be placed together, thus reducing the focus to 3 in., without any additional increase in the thickness of the glass. For the large flame of an oil lamp a couple of 4 in. plano-convex lenses of 6 in. equal focus mounted loosely in a brass cell, with the crowns almost touching (about $\frac{1}{8}$ in. apart), will give a lens of 3 in. focus, which will answer admirably for this class of work, but for limelight use, a meniscus or plano-convex back, and a bi-convex front of about 3 in. combined focus, will give much better results. With this combination some makers erroneously mount the lenses in such a manner that the meniscus side comes next to the picture, instead of which it should face the light in the lantern. The lenses should always be fitted loosely in the cells, in such a manner as to be capable of being readily revolved by means of the fingers; otherwise, the lenses (and especially the back one) may be apt to expand and crack upon the lantern being lighted up. One or two holes drilled in the brass cell will permit the escape of any moisture which might otherwise condense on the lenses. Compound condensers of 4 in. in diameter, and about $2\frac{1}{2}$ in. by 3 in. focus, are quite sufficient to cover the ordinary standard lantern slide, and this diameter should never be exceeded, except in the case of a condenser for a photographic enlarging apparatus, as a lens of larger diameter than the area of the plate to be covered means a corresponding loss of light. I had omitted to state that the lenses should be made of the best white flint glass, in order to get the best results, although a commoner variety is much in vogue by reason of its cheapness. Turning now to the objective, what you require is a short focus lens, which may consist of a couple of $1\frac{3}{4}$ in. lenses (a plano-convex and a meniscus) mounted close together, with the convex surfaces next to the source of light, and a stop in front of the meniscus (as shown in Fig. 1); this combination giving a lens of sufficiently short focus to allow of the lantern being placed at a distance from the screen about equal to the diameter of the latter. Such lenses, by reason of their necessarily short focus, will, however, give a slightly barrel-shaped distortion to square objects. A short focus photographic portrait lens will give a picture slightly fuzzy at the edges, which may be remedied by the use of a stop; but for lantern work this is inadmissible, as it means a considerable diminution in the light thrown upon the screen. The best method of overcoming this difficulty when space necessitates the use of a short focus objective is to employ one fitted with back lenses of large diameter. Short focus objectives are not, however, good to use at any time, as they disperse the light at an angle which interferes with the definition. Some good French portrait combinations—notably those made by Darlot—have large size back lenses and tolerably short focus, which render them eminently suitable for working in a confined situation. Although exhibitors are generally advised to employ an ordinary French quarter-plate combination for the objective of a lantern, they would find a considerable gain in the brilliancy of the picture by the use of lenses of larger diameter than the above, which seldom exceed a diameter of about $1\frac{1}{2}$ in., whereas an old-fashioned carte portrait lens of about 2 in. in diameter will pick up the rays of light much better, and give a more brilliantly illuminated disc. Fig. 2 is a section of the ordinary form of portrait combination, showing the disposition of the lenses. A serviceable objective can be constructed by an amateur by simply mounting together in a metal tube a couple of 2 in. plano-convex lenses of 14 in. focus, placing the crowns of the lenses close together, in a similar manner to a condenser. Longer focus lenses of this description should not be used. A still better objective can be made by making a couple of achromatic lenses, each of which is formed of a bi-convex lens of crown glass cemented by means of Canada balsam into a plano-concave lens of flint glass—the two lenses thus formed being afterwards mounted in a tube tolerably close together: plane sides of the lenses towards the screen. For objectives of, say, 6 in. focus, 2 in. lenses are best to use; and for 7 in., 8 in., or more, they may with advantage be $2\frac{1}{4}$ in. or $2\frac{3}{4}$ in. in diameter. Amateurs should bear in mind that good second-hand lenses can generally be purchased for considerably less than a novice could possibly hope to put one together for. As an example, Mr. Tyler, 48, Waterloo Road, S.E., a short time since offered some 4 in. condensers, the brass-work of which had got soiled, at 8s. each. Mr. Hughes, 82, Mortimer Road, Kingsland, publishes a second-hand list; so does Mr. Tyler; also Prof. Caplatzi, 1A, Chenies Street, Tottenham Court Road. A good selection of second-hand objectives, condensers, and miscellaneous lantern fittings can always be obtained from one or other of the above-named stores. —C. A. P.

Fig. 1.—Simple Form of Lantern Objective. Fig. 2.—Section of Achromatic Portrait Lens.

**Moderator Lamp Key.**—J. L. (*Somerton*).—Glad to find that my description of the moderator lamp, and how to clean and put it in order, was of service to others besides the original querist on the subject. As to whether or no it is worth your while to have a key fitted to it in place of the one missing, that depends upon whether you mind paying the extra cost for oil that using it will entail, for I must tell you candidly that they are expensive lamps to burn. If you have an old-established ironmonger in your town, he will be almost certain to have some of these lamp fittings in stock, either new or taken off old worn-out lamps.—R. A.

**"Fur" in Kettle.**—M. J. J. (*Aston*).—To clean the corrosion, or "fur," out of a copper kettle, dry it out thoroughly till it ceases to give out any steam; make it as hot as you can, and rap it sharply all over with a small mallet; let the blows be about equal in force, and well distributed over the kettle, so as not to bruise it more than you can help; the fur will then drop off the sides with the concussion. To clean the spout out, I always melt it out, heat it, treat it in the same way, and re-solder it in.—R. A.

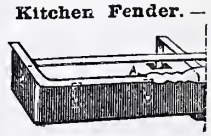
**E Puzzle.**—PUZZLED.—Your question is unsuited for WORK.

**Setting Quadrant of Slide-Rest for Turning Tapers.**—H. L. D. (*Strood*).—Suppose you have to turn the plug of a cock, and desire that it shall have a taper of 5 to 1, or that the diameter shall increase 1 in. for every 5 in. of length. You can proceed graphically thus: Take the diameter of your quadrant with callipers, and draw on paper a circle exactly the same size; from the centre of the circle draw a radius, and produce it beyond the circumference; draw a short line across the produced radius, at right-angles to it, and cutting it at a point exactly 5 in. from the centre; now measure from the point of intersection $\frac{1}{2}$ in. up the short line, and join this point with the centre of the circle by a straight line which cuts the circle at a point about $\frac{1}{2}$ in. above the first intersection; measure this distance very accurately with dividers, and it will give you the distance you must turn your quadrant from the zero mark to produce a taper of 1 in 5. Another way is by using a table of tangents. Suppose you wish to turn a taper of 1 in. per foot, or 1 in 12. Now, this is $\frac{1}{2}$ in. in 12, measuring on each side of the centre: $\frac{1}{2} \div 12 = \frac{1}{24} = \cdot 0416$, and this is the tangent of 2° 23′. If your quadrant is divided into 180 divisions, each division equals 2°, and you can set it to half a division for single degrees, but cannot estimate minutes or parts of a degree. If you want an accurate taper, there is nothing for it but measuring the taper itself.—F. A. M.

**Defects in Organ Pipes.**—F. H. (*Newington*).—Pipes may speak the octave above their proper note by reason of being over-blown, in which case stop off some of the wind by closing in the hole in the foot; or the upper lip may require cutting a trifle higher, or may require pressing in or drawing out in the case of a metal pipe; or the languid may require raising or depressing. Try the first recipe before tampering with the mouth of the pipe, and look to see that there is no dust or other obstruction in the windway. Weak tones are occasioned by similar defects, but remember that both dulciana and stopped diapason are intended to give a quiet tone; indeed, the latter would be ruined by trying to make it loud. Try giving a little more wind, and the upper lip of the dulciana may require cutting up a trifle. See that the stoppers of the stopped diapason fit truly, and are placed squarely in the pipe. If they lean over, or are not air-tight, the tone will suffer.—M. W.

**Wheel Cutting on "Go-Ahead" Lathe.**—(*No Address*).—I am sorry to find I have made a mistake in the drawing on page 61; the worm, W, could not be got in as drawn. INDEX will probably have noticed this, and seen that he must either make the worm solid and of no greater diameter than the hole for screw A, or else B must be bored out large enough to pass the spindle through it, and a sleeve fitted in afterwards as a journal.—F. A. M.

**Kitchen Fender.**—G. T. (*Castletown*).—The following sketch of kitchen fender will, I think, meet your requirements The front is made of sheet iron, the top of steel bars. The shaped piece from A is usually cut out in one piece, and then welded on to the bar.—T. W.



Kitchen Fender Plan.

**Paper Organ Pipes.**—F. W. (*Sheffield*).—Paper organ pipes can be obtained from Mr. W. J. Burton, Organ Builder, Winchester. I presume that the lengths given by you are the tone lengths of the largest pipes in the respective stops, as, doubtless,

you know that the smallest pipe may be only about ¾ in. long, whilst the 16 ft. tone can be obtained from a pipe 4 ft. long if it is a stopped pipe.—M. W.

**Bible.**—W. T. (*Bonnybridge*).—The leaves may be mended with tissue-paper and flour paste. Paste the edge of the tear and place a piece of tissue over it both sides, and when dry tear the tissue off again; this will leave a strip of tissue just where wanted. Let me know more definitely about the binding, and I will try and help you.—G. C.

**Phonograph.**—(*No Address*).—Your instrument seems to be all right so far as the construction is concerned, but your spring is too strong, and your needle certainly too blunt. Besides, I think that you screw the stylus, or needle, too far down, giving too much pressure upon the foil. Take note of these hints, and try again, and perhaps you may get better results.—W. D.

**Dividing Rules, etc.**—J. D. (*Poplar*).—A very fine graver is the proper tool to use, but you will require much practice before you can produce any satisfactory work, and can never approach the accuracy found in engine-divided scales.—F. C.

**Varnish for Screen.**—E. S. (*Liverpool*).—The rich dark polish and colour you have seen on writing desks, etc., can only be given satisfactorily to your screen by first darkening by means of stains, and finally French polishing. Varnish will not give so good a finish. You might try wiping over first with a weak walnut stain, and using just a tinge of red in your polish. An article, "How to French Polish," appeared in No. 105, March 21st; "The Rubber in French Polishing" in No. 108, April 11th. —Lifeboat.

**Stained Floor and Wax.**—Terpsichore.—To render your floor most suitable for dancing purposes, wax polishing is undoubtedly the best method extant, and if properly done, will not be "tacky," as you surmise, all tackiness being readily removed by finally wiping over with a piece of flannel, on the face of which has been sprinkled a little powdered French chalk; but for a large room it would be best to give the job to an experienced man, as it is laborious work in its first stages, though comparatively easy to keep in good condition afterwards. The fact that the floor is stained all over will make no difference if the present colour is suitable; otherwise, it must be done the right shade previous to polishing. Varnishing is often resorted to for the margins of floors, but cannot be recommended for the entire floor and the purpose you name. An article on Wax Polishing appeared in No. 52, page 826, from which you might glean many hints.—Lifeboat.

**French Polishing Fillers.**—S. S. (*Salford*).—The light oak may be oiled with clean linseed oil, and "filled in" by a mixture of finely-crushed whiting, just tinged with a little yellow-ochre, made the consistency of thick cream with turps or benzoline, rubbed well in crossways of the grain. For the satin-wood and maple you might omit the oiling first, also the ochre, using simply whiting mixed with equal parts of oil and turps; though for these light woods, including ash, some polishers use plaster of Paris and Russian tallow applied hot. This latter is a good filler, but its disagreeable smell prevents its general adoption; whilst others use plaster of Paris applied with a wet rag, and wiping off immediately: not left on all night, as I once saw done.—Lifeboat.

**Theatrical Limelight Apparatus.**—Stage Carpenter wishes to make a limelight apparatus for stage purposes. This may be said to consist of a wooden box of suitable size lined with metal, and mounted between a couple of standards attached to a base, something after the fashion of a toilet glass. A movable partition carrying a large size single condenser is made to slide into the box by means of grooves along each side, and a mixed limelight jet fitted to a tray moves along runners attached to the floor of the box immediately behind the condenser, connection between the gas bags and the jet being made by means of rubber tubing led through the back of the box, in a similar manner to an ordinary magic lantern. The coloured glasses (by means of which the varied tints are imparted to the light) slide into grooves immediately in front of the condenser. Some makers supply these coloured glasses mounted together on one circular disc or diaphragm, which is pivoted to the front end of the woodwork by means of a screw driven through a hole in the centre of the disc. This, of course, is very handy, as it does away with the chance of an accidental breakage. I will now describe a good useful form of limelight box, such as would be suitable for a 6 in. condenser. For the woodwork of the box (which should measure 10 in. by 10 in. by 12 in. when complete) obtain some *thoroughly dry* ½ in. or ¾ in. mahogany, preferably the leaf of a disused table, and proceed to carefully dress up three boards, each measuring 10 in. by 12 in.; and when ready, two of those which are to form the sides of the box should have a narrow groove run the way of the grain, at about 3 in. from one end, as shown in Fig. 2; after which, the three pieces are drawn for dovetailing, with the pins upon the floor or bottom piece. A narrow strip of the same wood, 10 in. by 3 in., which will also be required to form the top of the box, is merely intended for the purpose of binding the sides together, and should be placed across the top at 3 in. from the front end of the box, until just flush with the grooves, in which position it should be dovetailed to the sides. The framework can now be put together, with the grooves of the sides facing each other on the inside, using good glue for the purpose, and occasionally applying a square to the corners, in order that it may be got quite true. The base may now be prepared. For this, dress up a board to measure 11 in. by 14 in., and provide it with a couple of cross-ends, 11 in. by 2 in., which are screwed on in the manner shown in Fig. 3. A couple of standards, 9 in. long and 3 in. wide at the lower part, tapering to 2 in. at the top, are cut to the form of Fig. 4, and provided with dovetails, and next fitted into corresponding mortises prepared for their reception on opposite sides of the base; and before going further, it will be advisable to see if there is just sufficient room for the box to pass freely between the two standards. Returning to the box, a piece of ½ in. dry mahogany must be dressed up, and shaped and rebated on either side as shown in Fig. 5, until it slides smoothly along the grooves into the box; after which, a narrow slip of wood is nailed along the upper

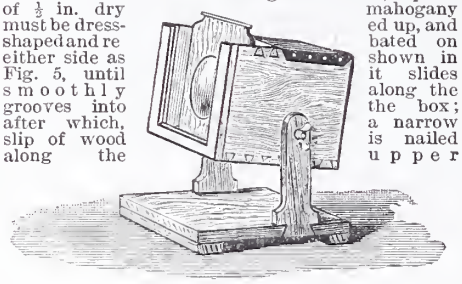


Fig. 1.

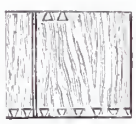

Fig. 2

Fig. 4.

Fig. 5.

Fig. 3.

**Theatrical Limelight Apparatus.** Fig. 1.—Limelight Box. Figs. 2 to 8.—Component Parts of same.

edge of the shaped portion as a finish. A circular aperture is now cut in the middle of this board, in order to receive the condenser, being provided with a slight rebate, against which to rest the lens. When ready, the condenser is retained in the opening convex side outwards, by means of a ring of cane, which is sprung into the aperture against the glass, and then pinned to the wood. This arrangement is far preferable to having the lens fitted into a mount, as it will be less liable to crack. The woodwork is now completed by screwing a strip of rebated moulding round the front end of the box, thus forming the requisite grooves for the reception of the coloured glasses. The shutter, which is used for the purpose of obscuring the light when not required, may be made from a piece of thin ply fretwood (to be obtained at any fretwork emporium), cut to the form of Fig. 6, and made to slide in the same grooves as the coloured glasses. The box will now require to be lined with a piece of sheet iron or tin plate, 27 in. by 9 in., with a central flap, 3 in. by 9 in., cut to the shape of Fig. 7, and bent in such a manner that the central portion may come immediately behind the condenser, with the short strip above the central portion bent out to right angles, in order to cover the narrow strip of wood across the roof, the remaining portions of the metal being required to protect the two sides of the box. The lining is affixed to the woodwork by means of short nails driven through holes punched in the metal. We shall now require another strip of metal, 12 in. by 6 in., cut to the form of Fig. 8, for the roof of the box, which is also nailed to the woodwork through the two sides of the metal which lap over. The box may now be hung between the two standards by means of a couple of bolts and fly nuts, inserted from the inside through holes cut through the metal lining of the inside of the box. It will thus be seen that the box can be retained in any desired position by tightening these bolts sufficiently. The remaining fittings, together with the management of the light, will be precisely the same as for an ordinary magic lantern, requiring the use of a mixed jet, and a bag each of oxygen and hydrogen gases under pressure, unless the compressed gas in cylinders is used, in which case an automatic regulator should be fitted to each bottle. Mr. Hughes, of 62, Mortimer Road, Kingsland, London, N., can supply 6 in. unmounted condensers, specially made for light boxes, at 16s. 6d. each. Also a special mixed jet at 12s. 6d.; any form of mixed jet will, however, answer as well. When a suitable jet has been selected, it will be needful to fit it on to an upright metal rod, attached to a board or shallow metallic tray, which is made to slide between a couple of grooved runners screwed to the floor of the box. Messrs. Cox & Co., 11, Fetter Lane, London, who advertise in the *Stage*, supply all requisites for theatrical limelight apparatus at low rates. The above firm quote coloured gelatine at 6d. per sheet, 7 in. square. This can be had in a great variety of tints, and may readily be mounted between a couple of sheets of glass of sufficient size in a wooden frame. The same firm also supply stained glass, mounted in frames, at prices ranging from 1s. 6d. to 2s. 6d. each. Messrs. Perken, Son & Raymont, of Hatton Garden, London, publish a little booklet at 6d. on the magic lantern, which will give you all the information you require on the management of the light, as the subject is one which cannot be treated at length in these columns; any special point shall, however, receive due attention.—C. A. P.

**Thermometer.**—A. X. E. (*Nottingham*).—Thanks for pointing out my mistake in stating, at page 828, No. 103, Vol. II., that in the construction of a thermometer the boiling point of water should *first* be marked upon the tube, whereas the authorities you quote show that the freezing point should first be ascertained and recorded. Please observe that in my reply to E. N., in the number of Work alluded to, I wrote that I had never made a thermometer, and that I gave the substance of the best description I could lay hands on at the time. This was taken from a source which I have always found most reliable—viz., Spon's "Workshop Receipts," 1st series, page 432, being the last article in the volume. Upon referring to this now, I find that my abstract of the description was correct, as the words are: "Distilled water is made to boil, and the thermometer surrounded with the steam produced; the point to which the mercury rises is marked off with a file, *and the freezing point of water is also marked.*" As I said in my original reply, articles on "How to Make a Thermometer" will, without doubt, appear in Work in due course, in which our readers will be fully instructed with regard to both theory and practice in the construction of this invaluable instrument.—Opifex.

**Stain.**—J. P. J. (*West Hartlepool*).—As you have only one sideboard you wish to darken, it is a question whether it would be worth the expense of making a special air-tight box in which to fumigate, especially as you say you have no room you could use for the purpose. Could you find such a room, or see your way clear to use the box for the same or any other purpose in the near future, it might be worth your while, as fumigation is pre-eminently the best plan to adopt, on the score of cleanliness and evenness of tone that is gained. You say bichromate of potash gives too red an appearance; this would be obviated by the addition of some walnut stain; or try either of the following: 1 pint liquid ammonia, 2 oz. Vandyke brown, 1 oz. bichromate of potash; mix 2 ox. pearlash and 2 oz. American brown potash in a quart of hot water. It may be well to remind you that it is always advisable to try the effect of these stains on odd pieces of similar wood to your sideboard, and thin down till you meet the desired shade, bearing in mind that the afterwards oiling, filling in, and polishing will, in all probability, make it a little darker still.—Lifeboat.

**Rust from Japanned Iron.**—M. M. (*Liverpool*).—The old japan will have to be scraped off with a plane-iron or similar instrument, and the surface scoured with dry grit-stone till the rust is completely taken out. If any rust is left it will be sure to spread, and again "throw up" the japan. As M. M. will probably have no convenience for the "storing" which black japan varnish or cycle enamel (which is in all material respects the same) requires, he will, perhaps, do as well to make shift with Aspinall's Enamel for re-coating his box, as he suggests.—S. W.

**Compo. for "Scriptograph."**—Eastwood.—The basis of all these "graph" compos. is glycerine and glue. That in question is composed of glycerine ½ lb., Russian glue, or gelatine, ¼ lb., water, and sulphate of baryta. The water is added to moisten as required; the sulphate of baryta is of no other use than to render the almost transparent mixture sufficiently opaque to show whether the writing has properly touched in every part; French chalk has sometimes been used instead. To prepare: first soak the glue, then put it into a jar standing in a saucepan of hot water; add water and glycerine, and when the glue is dissolved add the colouring matter (sulphate of baryta), and stir the whole together. When thoroughly mixed, pour warm into the shallow tin tray of the apparatus, and let it set. If it prove too hard, melt again with more water; if too soft and sticky, add glue. It is more than probable that the first one or two attempts will not be satisfactory. Or the compo. may be bought ready prepared from Messrs. Baddeley Bros., Chapel Works, Moor Street, London, E.C., at 2s. 6d. per tin.—S. W.

**Staining and Book.**—G. J. W. (*No Address*).—There are several books published treating of the subject. I have not seen one yet that can be recommended to the amateur, though Messrs. Wyman & Sons, 74, Great Queen Street, London, W.C., issue one in their Technical Series, "French Polishing," price 2s. 6d., which is of more service to the professional than embryo polisher. Far and away the best to be recommended to the learner is the series of articles commencing in the present

lume of WORK, the first of which, "How to ench Polish," appeared in No. 105, March 21st, d "The Rubber in Freneh Polishing," in No. 108, ril 11th, to be followed by others besides. Had u read this paper closely, and the answers given "Shop," you could not fail to have gleaned many eful hints. Have you no bookseller in your neighurhood who would be glad to supply you with numbers of "Natural History" you require? If t, write Messrs. Cassell & Co., asking for a classid catalogue of books, and stating your requirents.—LIFEBOAT.

**Enamel Paint.**—H. A. K. (*Bedale*).—The nearest proach to be obtained by self-mixing is to use a hite enamel, or Bath, varnish, and add to it finelyound tube colours. Ordinary paste paints are not fficiently finely ground for the purpose; even the st white lead of ordinary paste form will dull and ake gritty the enamel or varnish. If white is anted, tube flake white can be used, from which nts of any colour can be made. See Index, Vol. I., r Picture-frame Compo.—F. P.

**Gold Bronze.**—J. D. (*London, E.C.*).—Gold ronze—viz., bronze powders—may be used in quid form by making a solution of white stick lac methylated spirit, and adding the bronze thereto. ufficient only of the lac must be used to bind the owder, or the brightness of the bronze will be ffected.—F. P.

**Banjo Fittings.**—P. Q. (*Denholme*).—Did you see dvertisement in advertising columns for fittings? ou can get ordinary fittings from Messrs. Dawkins, harterhouse Street, London. The portable music tands (folding iron) are patented, therefore you ould not make them. Even if you could buy the arts, they would very likely cost you as much as ou could buy the stands for finished. If you write o Messrs. Harrow & Co., 13 and 14, Portland Street, Vardour Street, London, W., they will, no doubt, ive you all particulars.—J. G. W.

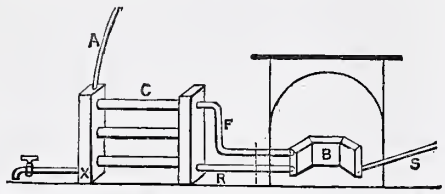
**Electric Light for Dark Corner of Room.**—N. B. E. (*Walsall*).—You will find full instructions n small electric lights in the articles published in Vol. II. on "Model Electric Lights" (see Nos. 76, 82, 9, 92, 94, 97, 99, 101, and 104). The little arrangenent for a photographic dark room described and llustrated in No. 89, page 593, will just suit the urpose of persons like yourself, who wish to have small light at the smallest possible cost.—G. E. B.

**Strength of Electric Current.**—LEARNER.—Your friend was quite right, but you have drawn a wrong inference from his statement, and have mixed up current strength with E.M.F., or current potential. The strength of an electric current is expressed in ampères, which represent the total volume of current obtainable through a given resistance when urged by a certain pressure or potential. We first of all take the potential, or electric pressure in the cells; this, in the battery you name, is 1½ volts each cell. To obtain 1 ampère of current from one of these cells, the total resistance of the whole circuit must not exceed 1½ ohms. If, then, the resistance of the motor is 1 ohm, and you get 1½ ampères of current through the motor, the resistance of the cell itself would be nothing. This course of reasoning is ridiculous, as the cell must have an internal resistance. Suppose it to be a large Leclanché cell, having an internal resistance of ¾ ohm: then the resistance of the cell will be ·75 ohm; the resistance of the motor 1 ohm: total, 1·75 ohms. Now, the E.M.F. of the cell is 1·50 volts. Divide the total E.M.F., 1·50, by the total resistance, 1·75, and we get ·85 ampère as the total strength of current. Now add another cell in series. The result will be $\frac{1{\cdot}50 \times 2 = 3{\cdot}00 \text{ volts}}{{\cdot}75 \times 2 + 1 = 2{\cdot}50 \text{ ohms}} = 1{\cdot}20$ ampères. If we take a smaller cell the internal resistance will be higher: say 1 ohm instead of ¾ ohm; then the result will be, $\frac{1{\cdot}50 \times 2 = 3{\cdot}00 \text{ volts}}{1{\cdot}00 \times 2 + 1 = 3{\cdot}00 \text{ ohms.}} = 1{\cdot}00$ ampère only. The consumption of zinc will be proportional to the ampères of current obtained, not the volts. The strength of current in ampères at the terminals of a secondary coil will be very small indeed, but the potential is enormously increased by the inductive effects of the coils of wire.—G. E. B.

**Slipping of Driving Belts.**—BELTING (*London*).—As I have not yet met with a good composition to prevent slipping of belts, I am sorry to say I cannot recommend one to you. All that I am acquainted with are injurious to leather belts, and more or less dirty in use. I am, therefore, an unbeliever in the efficacy of belting compositions. The supposed necessity for their use arises out of bad arrangements for driving the machines. If belts of the right width, made out of best raw hide leather, well oiled, are employed in the first instance, and the pulleys are properly proportioned, there will be no slipping of the belts, providing, of course, they are not too slack or too tight. If you will give me full particulars respecting the driving arrangements of your dynamos, I will endeavour to advise you how to prevent slipping of the belt.—G. E. B.

**Indiarubber Substitute.**—G. A. & Co. (*Stockport*).—We do not find any patent issued for the material mentioned under the name given. So far as we have learned, it was a failure, and did not fulfil what it was proposed to do. We are unable to give the address, not having been able to ascertain it, and from what we can learn, little benefit would be derived from it were we able to do so.—C. E.

**Portable Coil.**—W. A. T. (*No Address*).—If you mean an ordinary coil, such as is used to warm an entrance-hall, staircase, and so on, which is constructed of cast-iron or copper pipes, and is heated from a boiler in another part of the building, I say, "No, it is not practicable," as I presume you want to take it from one room to another; and there are various reasons why this could not very well be done. I do not say it is impossible. I send you a sketch showing how it *may* be done. B is the boiler, which is placed on the stove to form the



**Small Coil heated from Register Grate. B, Boiler, taking place of Fire-bricks. F, Flow-Pipe. R, Return-Pipe. C, Coil. A, Air-Pipe. S, Supply-Pipe. The dotted lines show where Valves would have to be put if Coil is to be removable.**

fireplace; C is the coil, which may be in the same room, a room adjoining, or a room beneath. The flow-pipe goes in at the top, and the return comes out at the bottom. If this coil is to be fixed so as to be removable at any time without disturbing the pipes, and so that it can easily be put back again, a screw-down stop-valve must be put in each pipe, with a connector in each pipe on the coil side of the taps. Some provision would have to be made to run the water out of the coil after the valves are turned off, before disconnecting—say a short piece of pipe with a tap at X. Water to supply the coil could either be taken to the boiler from a supply cistern, or the coil boxes could have loose covers, so that water could be poured into them occasionally, the waste from evaporation being small; in this case no air-pipe or tap would be required. Rippingilles—the oil-stove people—make several hot-water arrangements for use with their stoves; and probably one of them would answer your purpose better than the above, which, though movable, can scarcely be called portable.—R. A.

**A Doll's House.**—H. M. (*Hunsdon*).—Many family men are numbered among our readers, as is evidenced by the numerous applications received for designs of cots, bassinettes, etc., and, in the present instance, a doll's house. Overcrowded space prevents much from being said concerning constructive details, therefore, a great deal must be

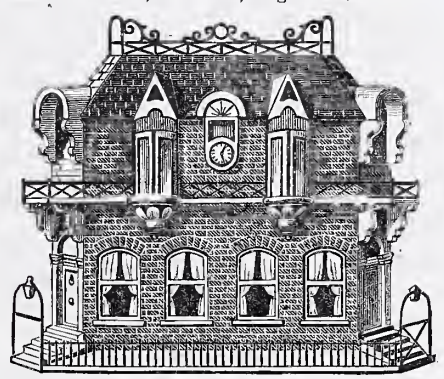


**Fig. 1**

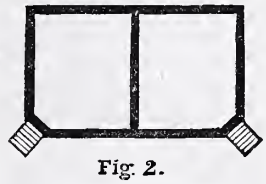

**Fig. 2.**
**Model Doll's House.**

left to the reader's judgment and opinion. In this design I have studied simplicity of construction; and sufficient opportunity exists for ornamental details to an unearrying limited extension. A ground plan is shown in Fig. 2, in which is indicated what I consider to be the best positions for doors. If these ends are fitted merely with windows, with the halcony also returned along them, such should suffice for effect. It will be preferable to make a rough cardboard model as a preliminary object of ascertaining the proper proportions and shapes of the various parts. The roof and its adjuncts will be found the most difficult part to construct. If a partially flat roof is adopted, the possessor of the house will value it the more. I would suggest that instead of carrying the ends entirely to the top as doors, the roof should open flap-wise, and the upper storey of the house be fitted as a work-box. You are going to make one 3 ft. high with four rooms; but, as will be understood, the design is not confined to one particular enlargement.—J. S.

**Flute Cases.**—S. G. F. (*Chiswick*).—The flute cases used by the bandsmen of the Guards' Drum and Fife Band are made of the best bleached buff, and are hand-sewn. They cost about 12s. 6d. each, but lower-priced ones are procurable. Apply to Messrs. Silvani, 45, Wilson Street, Finsbury.—G.

**Circular Rails.**—F. B. H. (*Wolverhampton*).—The smallness of diameter of the rail track will be limited by the amount of clearance you can give the flanges, and this will depend upon the width of the wheel treads, which you do not mention. If there were no play between the flange and rail a straight track would be necessary. Your simplest course is to make a short piece of track of stout tin plate, and so determine experimentally the shortest radius at which the flange of the leading wheel will not mount the rail. The outer rail should be raised slightly above the level of the inner rail, to counteract the tendency of the engine to fly off by centrifugal force. To find the necessary super-elevation of outer rail in inches above the inner rail, multiply the gauge of rails in inches by the square of the speed in miles per hour, and divide the product by the radius of track in feet and by seventy-two.—F. C.

**Beam Engine.**—J. B. (*Edenfield*).—Consult carefully the Indexes to Vols. I. and II. of WORK now published, and if there is no answer to your questions, kindly repeat them.

**Castings.**—CORINTHIAN.—Special tools must be made to suit special tasks. Generally speaking, those used by engravers, and also the metal shapes and burnishers used by fitters, are suitable. They are employed in similar fashion.—J.

**Engraving Drawing Instruments.**—DRAUGHTSMAN.—I recommend you to put them into the hands of an experienced engraver, who will do justice to them. Another way is to have them etched, for details of which please refer to No. 84, Vol. II., of WORK. You will find something about "Engraving on Metal" in Nos. 33 to 48, Vol. I. The special Exhibition Number is *not* intended to be bound in the case supplied by Messrs. Cassell & Co. for the ordinary volume of WORK.—N. M.

**Transfers for Coach-Work.**—(*No Address*).—The leading artist herald painter of the coach trade is Mr. John Sneath, Herald Painter, of Grantham, Lincs.; he is reliable for accurate delineation and work of the highest class in transfers. Leigh Anderton, Heraldic Artist, is also a first-class transfer artist; his address is 67, Vine Street, Manchester. For plain decorative work in transfers and heraldpainting transfers, Charles Witham, 22, Grove Street, Lisson Grove, N.W.—J. C. K.

**Setting a Razor.**—K. L. (*No Address*).—If K. L. will kindly hunt up No. 100, Vol. II., of WORK, and turn to "Shop," page 782, he will, I think, find all he wants to know on the above subject, though rather condensed. Two of the sketches might have been plainer, but I have no doubt it was owing to want of space. The razor is laid flat on the stone, and when holding the handle with the right hand, three or four fingers of the left should press the razor pretty strongly on the stone during the period when the sharp edge travels first—that is to say, just the opposite to the method of stropping. When returning for another stroke the pressure should cease entirely, or almost so.—P. B. H.

**Painting Mottoes on Carriages.**—H. W. (*Strabane*).—The fine work of heraldry is, like miniature painting, done with suitable brushes. The mottoes being simply conventionally imitative in execution, are not difficult with panels in good position for light and work. The subtle touches which shall give character to a face, or display a definite expression to animal form and aspect, is real art, and requires more careful selection of brushes than for motto writing. Sable brushes are used, being stiffer for touch than camel-hair, which serve best for surfaces or lines in the arms. Pens cannot be used with oil paints effectively. Major Middleton, a most successful artist for limning the character in the face of his study for a portrait, had a very small picture to execute, which required the high lights to be well marked, as in heraldry they are invariably done. He came for a day's shooting to the writer's land, "in search of his tools," he said; that was two fine and very small feathers, to be found only in the pinions of the woodcock. They are very fine pointed, with very slight flexibility, and just that imbrication of feather which will take up a pigment and release it easily, even to the smallest dot ever wanted in miniatures; they serve this purpose, and none other, in artists' work.

**Woodcock's Feather.**

**How to make a Greenhouse.**—WHEELBARROW.—In Nos. 12, 14, and 16 of WORK you will find the construction of a greenhouse thoroughly and practically dealt with.

**Grinding Scissors.**—W. B. (*Penna, U.S.A.*).—We have not the address of H. F., the reader to whom you wished us to send on your sharpener.

**Mathematics.**—F. K. (*Oldham*).—Write to Messrs. Cassell & Co., Publishers, London, E.C., for their list of school books.

**Bow-Hairing.**—J. B. (*Leicester*).—This subject requires a short paper, with illustrations.—B.

**Violoncello.**—NO NAME (*Glasgow*).—Send through the Editor, prepaid, a pencil outline of the instrument you intend to make, and I will give the thicknesses and measurements you ask for.—B.

**Electrical Measurements.**—E. G. (*London, N.*).—The volt is the recognised unit of electric current pressure, and is roughly represented by the difference in potential between the zinc and copper

elements in a Daniell cell. The ohm is the recognised unit of resistance to the electric current, and is roughly represented by 6 ft. of No. 36 pure copper wire. The ampère is the recognised unit of electric current volume, and is represented by the quantity of current forced through 1 ohm of resistance by 1 volt of current pressure. For exact measurements, there are measuring instruments constructed to measure the current pressure and the resistance. To find the resistance of a Leclanché battery, you will need a delicate galvanometer—*i.e.*, current indicator, a set of resistance coils, and a Wheatstone bridge. The bridge will correspond with the beam of a balance; the resistance coils will represent the weights; and the galvanometer the index pointer of the balance. The resistance of the battery is balanced against the known resistance of a number of the coils. A detailed account of the process would occupy too much space in "Shop." In answer to your other questions:—(1) Supposing each cell of a Leclanché battery gives a current pressure of 1½ volts, and each cell has an internal resistance of 1$\frac{2}{10}$ ohm, then the ampères of current obtainable from any number of cells placed in series will equal the total voltage as multiplied by the number of cells, *when divided* by the total resistance of all the cells and all the conducting wires. (2) The resistance is known by balancing it against a known resistance by means of the instruments mentioned above. (3) You will now see that resistance is a factor apart from current pressure and volume, as expressed by volts and ampères, therefore your third question means nothing at all. —G. E. B.

**Dressing Tarpaulin Sheets.**—A. W. T. (*Willesden New Junction*).—We apprehend A. W. T. wants to dress already made what he terms tarpaulin sheets which have been in use. Now, before we can give him any useful information on the subject he must let us know what kind of sheets he refers to, as although nearly all waterproof sheets or covers are, in common parlance, called tarpaulins, it is by no means a fact that one in a hundred is a "tarpaulin"; and unless we know exactly what kind of sheets he refers to, might give him quite wrong information, which we are by no means desirous of doing. In order that A. W. T. may see and understand what we mean, he must remember that in one class the waterproof qualities are obtained by means of a medium which is coated *on* the surface; in another class they are obtained by a material placed or included *between two* surfaces; and in the other by means of a material which *permeates* entirely through the whole of the material forming the sheet. A. W. T. must understand that what produces the desired effect in each particular case would cause entire failure and injury if applied to either of the others.—C. E.

**Taking out a Patent.**—F. S. S. (*Leicester*).—No invention patented in this country can be made abroad and imported by any foreigner or Englishman during the duration of the English patent. Of course, when the exclusive right has expired, it can be made by anybody anywhere, and imported or exported, as may be the case. It is perfectly free for a foreigner residing in any country where the invention has not obtained exclusive privileges to manufacture and sell the invention; but he cannot sell in or send them to any country where the inventor has obtained an exclusive privilege. There is no such thing as "protection," in the sense in which it exists in England, in any of the foreign countries. In these you have to apply for the grant of a patent, and deposit a complete specification, claims, and drawings, with the application; and when the patent is granted you have then got your rights and protection. The cost of all this entirely depends on the work to be done, the time it occupies, the cost of meeting the objections raised by examiners—most particularly in the case of the two latter countries named—and various other points connected with the work. We would advise F. S. S. to refer to, and read and study, the article on this subject in WORK, No. 44, Vol. I., p. 694; also the reply to R. W. S. (*Leeds*), in No. 109, Vol. III., p. 77.—C. E.

**Reproduction of Draughtsman's Drawings.**—ON TIME.—To reproduce drawings in the manner required by ON TIME, the drawings have to be traced on what is known as autographic transfer-paper with a peculiar ink, and then transferred to the plate, from which any number may be printed. We do not gather from the query whether it is desired to know the *modus operandi* of the process, or whether it is simply desired to know what is the best ink for the purpose. Lithographic or chemical ink may be used, which should be rubbed dry on a clean porcelain saucer until sufficient is rubbed off. Then add water, drop by drop, until sufficient is added to make it, when rubbed with the finger, of a deep black colour, and liquid enough to flow evenly from the drawing pen; but it will not do if it is at all "watery." Great care must be taken to keep it perfectly free from dust when in use, and if it is allowed to become dry it should be thrown away, and a fresh lot mixed, no satisfactory results being obtainable by re-mixing.—C. E.

### III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Windmill Sails.**—TURNER writes:—"Can anyone tell me the length (from axle to end of whip) and breadth of windmill sails to develop at twenty revolutions per minute—1st, 5 h.-p.; 2nd, 10 h.-p.; 3rd, 15 h.-p.? Also I shall be glad of a sketch showing action of and method of coupling up of louvre-board rods. Average velocity of wind, twenty miles per hour. I give number of revolutions per minute and velocity per hour as two foundations to calculate horse-power on. I hope I am sufficiently clear."

**Oak Mouldings.**—T. J. J. (*Tottenham*) writes:—"Will any reader kindly inform me where I can obtain small oak mouldings and beadings, suitable for a small bookcase, about ½ in. or ⅝ in., anywhere round Shoreditch or the City?"

**Thin Lines in Fretwork.**—PUZZLE wants to know how to cut in fretwork very thin lines in the middle of a design. If he bores a hole, it makes the work look ugly at once.

**Glass Writing.**—E. E. D. (*Crewe*) writes:—"Can anyone inform me where to obtain a book on glass writing and embossing; also, how to mix isinglass and spirits of wine as used for size for gilding on glass?"

**Fan Blowers.**—W. H. (*Motherwell*) writes: "I shall feel obliged to any reader who will give me full particulars and dimensions of a useful set of fan blowers."

**Preservative for Outdoor Polished Brass.**—P. H. (*London*) writes:—"Can any reader tell me a simple recipe for preserving a brilliant polish on outdoor brass-work (handsome knockers and letter-box plates on front doors)? I have tried several kinds of enamel and lacquers, including 'Silicon,' but to no purpose, although it answers for indoor work. I have used a special preparation of vaseline, but it spoils the gloves and greases the hands of those who have to use the knockers, etc., and, besides collecting dust and dirt, it shows tarnish in a fortnight, and wherever the fingers have touched it it turns black in an hour. I have not time to spend a half-hour every day to clean them with polishing paste; besides, if then left two or three days, they get so black that it takes three hours or more to clean, only for them to go black again in two or three days."

**Fire Balloons.**—E. D. R. (*Brierley Hill*) writes:—"(1) Will any reader kindly inform me how to make coloured fire to illuminate the bottom of fire balloons? (2) How to fix same? (3) The probable cost?"

**Letter-Press Printing.**—W. A. D. (*New Brompton*) writes:—"Would anyone inform me where I could obtain (and the price of) a good practical work on Letter-Press Printing?"

**Air Pump.**—A. T. (*East Greenwich*) writes:—"Will any reader of WORK tell me how to make a pump for pumping air, and show diagrams in 'Shop?'"

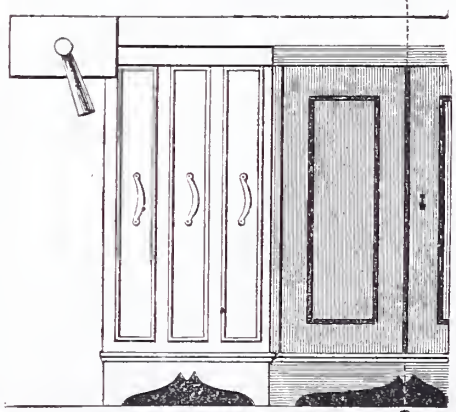
**Air Cushion.**—H. R. (*Clapham*) writes:—"I have an air cushion which has a slight leak. Can any reader inform me how I can find out where it is, so as to repair same?"

**Fret Clock Design.**—H. O. H. (*Bristol*) writes: "Will any reader of WORK tell me where I could obtain a good clock design for fretwork, either Italian or French preferred? Also where I could obtain a catalogue of French miniature designs?"

### IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Petroleum Motors.**—THE BRITANNIA COMPANY write:—"In reply to CONSTANT READER (see page 142, Vol. III.), petroleum motors cost more for fuel than gas or steam-engines, except in districts where petroleum is produced. In towns where gas is above 5s. per 1,000 the difference is not so important. There are two good petroleum engine makers who supply various sizes."

**Combined Bench and Tool Chest.**—F. A. (*No Address*) writes:—"In reply to T. R. B. (see page 142, Vol. III.), I send a design for a combined bench and tool chest. The drawing shows one half, the other half being exactly the same (of course, with the omission of the vice). All patterns of tool cabinets, as at present made—*i.e.*, with cupboards at the ends—require about 1 ft. 6 in. extra space at each end to allow for opening. This is obviated by having slides at A (which are really three drawers turned on end, and with racks for tools). Of course, these do not require any room at the end, which, as T. R. B. requires one end of bench to stand against wall, could not be spared. A B is a cupboard, set back about half the width of the bench, for large tools, glue-pot, etc. The lower portion should be made in three carcases, screwed to the top of bench and to each other, to allow of easy removal."



Combined Bench and Tool Chest.

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—ST. MUNGO; J. D. (*Glasgow*); I. R. C.; H. W. (*Bristol*); J. # PHOTOGRAPHY FOR AMATEURS.

A Non-Technical Manual for the Use of All. By *T. C. HEPWORTH, F.C.S.* With Illustrations, and Full List of Dark Rooms available for Amateurs throughout the Kingdom.

"One of the most thorough and efficient manuals for the non-professional photographer has been written by Mr. T. C. Hepworth. It deals with everything which an amateur should know, not from a hazy, semi-scientific point of view, but from a really practicable standpoint. All the many difficulties which amateurs are likely to encounter, and the many errors into which they are almost certain to fall, are foreseen and provided against, while numerous ingenious hints are given so as to make the amateur's labours as easy as possible. Mr. Hepworth has an intimate knowledge of photographic science, and his book will be welcomed by all amateurs."—*Graphic.*

VOL. III.—No. 119.] SATURDAY, JUNE 27, 1891. [PRICE ONE PENNY.

## A MODEL RUSTIC TOOL-HOUSE FOR A SMALL GARDEN.

BY ARTHUR YORKE.

MATERIALS—THE WALLS—THE ROOF—FITTINGS.

*Materials.*—In this miniature rustic building, the materials used are what are known as "slabs" or "rough planks." These are cheap, and have, when judiciously handled, a good picturesque effect. For those who do not know them, I may explain that these slabs are the outside slices, of which two are cut from every log of rough timber when it is sawn into boards. It is only our native trees which furnish them, imported timber being hewn square before it is sent to us. These slabs generally retain their bark (except in the case of oak), and in most districts they will commonly be of elm. Their thickness and outlines are necessarily irregular: one end will frequently be narrower than the other; and this will account for the arrangement seen in the walls and door of our building. They are to be bought at saw-mills, or wherever sawing is going forward; and as they are not looked upon as a marketable part of the timber, they are sold at a fire-wood price merely. Where their cost is not sensibly increased by carriage, no other material comes so cheaply for building rough sheds. The ordinary country way of using them is as in the horizontal section, Fig. 4.

This plan, however, is not suitable for our purpose. In so small a structure, rough planks on the inner side would too much interfere with our space. It is, therefore, proposed to straighten the edges, either by sawing or by chopping with the axe, according to circumstances, and lining their inner sides with thin board. If the cost be not objected to, half-inch match-boarding will be neatest for this purpose; if economy is an object, the boards of packing-boxes, bought from the grocer, might suffice. There are, it will be seen, three sides only to be lined.

Among a lot of rough planks, it is likely that stuff may be found sufficient for the posts and other scantling, but as this is uncertain, I have shown these matters as of regularly squared stuff. As to the six pilasters, which are added for appearance merely, it is possible that stuff might be found which would, when sawn to width, do for them; but I have rather supposed them to be fir poles or elm saplings; four sticks only are needed to supply the six halves and four quarters used.

*The Walls.*—At the corners are four main posts, 4 in. square. These are shown at *a*, *a*, *a*, *a* in the ground plan. Fig. 3. These enclose (outside

Fig. 4.—Common Method of using Slabs.

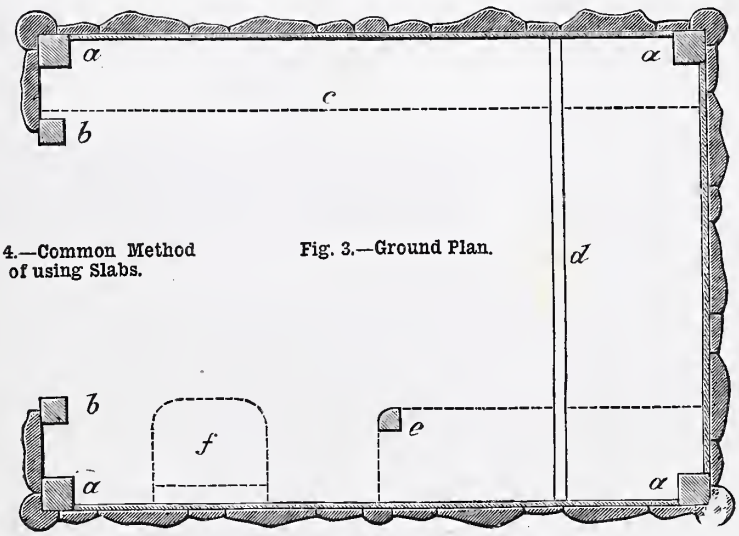

Fig. 3.—Ground Plan.

Fig. 1.—Elevation of End.

Fig. 5.—Cap of Pilaster (Enlarged).

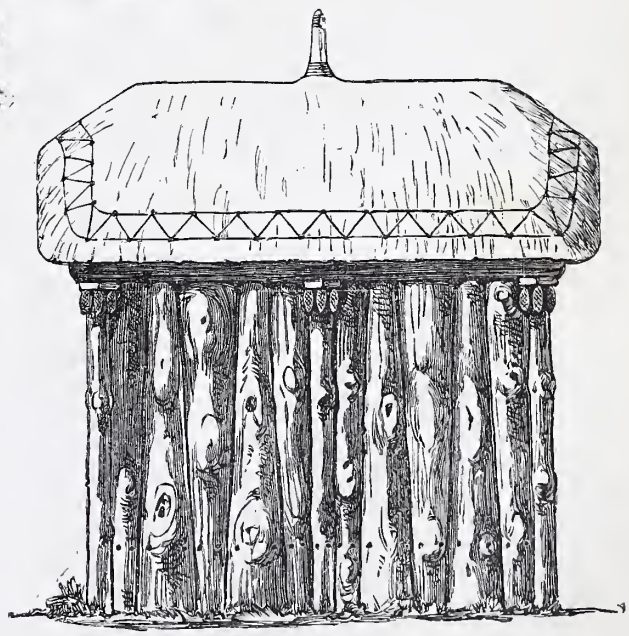

Fig. 2.—Elevation of Side.

measurement) a space of 7 ft. by 5 ft. They are let into the ground 2 ft., and rise 5 ft. 3 in. above the ground line.

On their tops, and coming flush with their outer edges, rest the wall-plates, which are 3 in. deep; these are needed at the back and sides only, and not at the front. On the same three sides will also be cross-rails, 2 in. to 3 in. thick, the ends of which will be let flush into the posts about a foot from the ground. To the wall-plates and these rails the slabs are nailed. In the side elevation, Fig. 2, the nails driven into the cross-rails appear, but not those driven into the wall-plate, a piece of rough stuff being there shown as fixed over the latter to support the eaves of the thatch.

To the front are to be seen the two door-posts, *b*, *b*, Fig. 3, which are 2 ft. 8 in. apart, and should be about 3 in. square. As their tops are nailed to the front pair of rafters, they rise to a height of 6 ft. 6 in. The space between door-post and corner-post is filled up by a single slab nailed to the two—5 ft. 6 in. long by 10 in. broad. Above these, instead of a wall-plate, comes the piece of strong slab, shown in Fig. 1 as having an opening cut in it for the head of the door. This is nailed against the door-posts, rafters, etc.

The pilasters are only a matter of ornament. As drawn, they are of halved stuff; the corner ones are so placed that their middles come opposite to the corners of the posts, on the other faces of which pieces of quartered stuff are nailed to meet them. The simple arrangement of the caps of these pilasters, with their decorations of fir cones, is shown on a larger scale in Fig. 5. The horizontal piece beneath the eaves, nailed over the slabs, has the effect of resting on the caps. Beneath the thatch at front and back corresponding pieces are fixed, those at the front being ornamented with fir cones nailed upon them.

*The Roof.*—This is shown in the elevations as thatched. No other covering will look so well, or be so thoroughly in keeping with other parts. The non-professional builder finds it easy to prepare for thatch, any rough stuff serving as rafters and laths, and no accuracy being needed in putting them together, since the thatcher, with his accommodating material, is able to make up any inequalities. The rafters for thatch should be arranged about 1 ft., the laths about 6 in., apart. In the article on Summer-Houses, Vol. II., page 67 (No. 57), it will be seen that more is said on the subject of thatch and thatching for rustic buildings.

Should there, however, be reasons for not employing this mode of covering, our building may be more quickly and easily, if not more cheaply, roofed with galvanised iron; only the gables will then best be made sharp instead of blunt, as at present.

*Fittings.*—Of these, the door should first be mentioned. Its outer slabs which appear in Fig. 1 are simply nailed to three ledgers of the same. Being of such rough materials, it will open better if hung on hooks and thimbles than on hinges.

As the space within will be strictly limited, we must take care that everything has its proper place—there is not room for confusion. The dotted line at *c*, Fig. 3, marks the projection of a set of shelves, about five in number, which fill the whole of the left-hand side. Of these, the lower will be for flower-pots, the upper for lines, setting-pins, trowels, etc. At *d* is shown a strip of wood fixed across the floor to hold the wheel of the barrow from running back when that useful vehicle is tilted up against the end wall, which will be the place assigned for it. In the gable and upper part of this end will be hooks or pegs on which to hang the riddle, watering-cans, and such matters. At *e* is an upright let into the ground, which, at the height of 2 ft., supports rails running to side and back; these form a kind of stand for spades, forks, and tools of that description. Above, against the wall-plate, may be more hooks or pegs.

It is suggested that at *f* a seat might be fixed to fold down like the leaf of a table when not wanted. As this building would form a snug shelter in a shower, such a seat would be a convenience; but the more important use of this space is that slightly below the level of the eaves it will be fitted with a rack for hoes, rakes, and similar implements. Such a rack is best made by boring ½ in. holes in a strip of wood at intervals of 3 in., and driving pegs into them 5 in. or 6 in. long. This has to be nailed so that the pegs will slope upwards, at an angle of about 45°. Rakes, etc., hung in a rack so made cannot fall.

Figs. 1 and 2 are ¼ in. to the foot; Fig. 3 is ½ in. to the foot; but Figs. 4 and 5 are not drawn to scale.

## FRENCH POLISHING—MORE ABOUT BODYING IN.

BY DAVID DENNING.

APPLIANCES NECESSARY—DESCRIPTION OF PROCESS—MOISTENING WADDING—TOUCHING RUBBER WITH OIL—APPLICATION OF MORE POLISH—HOW LONG TO CONTINUE FIRST BODYING IN—CONTINUATION OF PROCESS—SAND-PAPERING—CLEANLINESS NECESSARY—DRYING RUBBERS—EDGES.

ENOUGH having now been said about the polish—*i.e.*, the material—we may see about using it for bodying up. The wood, it may be assumed, has been prepared by filling of one kind or another, as fully explained in a previous article, and rubbed down smooth with the finest or worn glass-paper, to make it in a fit state to receive the polish; for it will easily be understood that a high degree of finish cannot be got on a rough surface. The rubber with which the polish is applied has also been sufficiently fully treated of elsewhere, so that nothing more need be said here about its preparation beyond that it consists of cotton wadding with a soft rag cover.

Wood, rubber, polish, and a little raw linseed oil being ready, bodying in may be proceeded with.

Moisten the wadding with some of the polish; put the rag cover on, being careful that at the bottom it is even and smooth, without any folds or wrinkles. Then, to distribute the polish evenly throughout the rubber, and cause it to moisten the rag at the bottom properly, dab the rubber into the palm of the left hand. The rubber is now ready for application to the wood, and the real work of polishing begins. Naturally, the beginner will not attempt to polish anything large at first, and it may, therefore, be supposed that he has got a piece of work which can conveniently be managed; and it may be well to remind him that his aim should be to spread the polish equally over the surface. The exact way in which this is done must depend to some extent on the shape of the wood, and also on the habit of the polisher; but, supposing it is a panel or flat surface which is being treated, the following method will be found as good as any, and is one that is more or less followed by experienced polishers.

Briskly rub across the grain, just to get the surface covered; then proceed by a series of circular movements, as shown in the diagram in page 54, to go over the whole of the work with a moderate amount of pressure, which should be gradually increased as the rubber dries, but at no time should the movement degenerate into mere scrubbing. In order that the rubber may work smoothly without sticking, its face should be just touched with a little of the raw linseed oil. The less of this used the better, and if it could be dispensed with altogether no harm would be done. Unfortunately, however, it cannot well be dispensed with, and the only thing is to use as little as can be managed with to make the rubber work smoothly. A very little will suffice. Just moisten the tip of a finger with oil, and touch the face of the rubber with it; that is all that is required. The rubber certainly must not be dipped in the oil, nor must the oil be dropped or poured on it from a bottle; for by any of these means more oil would be applied than is necessary—in fact, instead of being an assistance, the oil would prove fatal to good work.

As the rubber dries, more polish must be applied to it, as in the first instance, with oil as required. A very small quantity of polish goes a long way, and I must impress upon the novice the necessity of not making the rubber too wet. It should be fairly moist, and nothing more. Perhaps the best way to explain, to those who are unacquainted with the process altogether, what is wanted will be by comparing the rubber to a sponge, and illustrating what is wanted by means of this and water. Saturate the sponge with as much water as it will hold, and, supposing it to be a rubber with polish, it will be far too wet. Squeeze out some of the water till none drops from it if not squeezed, but leaving sufficient in to run out on the sponge being rubbed on anything hard. Still too wet for polishing purposes. Now squeeze all the water out till the sponge is almost dry, and will just damp anything on which it is rubbed without water flowing from it. This is just about what is wanted with the polishing rubber, and for ordinary bodying in it should never be wetter.

But, perhaps, many a beginner, noticing how tedious the work is with such a dry rubber, may be inclined to think that if he used more polish at a time the desired result would be more quickly attained. Well, if the object were merely to get the wood coated anyhow, this might be the case; but the result of using too much polish would be that, instead of a fine even coating or body, the shellac left by the evaporation of the spirit—and it is almost unnecessary to say that the spirit evaporates quickly—would be ridgy and irregular. Anything at all approaching a flow of polish from the rubber must be avoided. On the other hand, if the rubber is not sufficiently charged with polish, the labour of bodying up will be unduly protracted, if not rendered impossible, from the fact that no polish can be rubbed on to the wood.

The bodying in should be continued—that is to say, the first one—till it seems that the wood absorbs no more of the polish. There will be a perceptible gloss on its surface, but it will be streaky, and show the rubber-marks very distinctly. Never mind that, though, for all these marks will be removed later on—at least, let it be hoped so, for directions how will be given in due course.

It may be said that, if the polish is too

thick or too thin, the results will be very much the same as if the rubber were too wet or too dry. As it may be difficult for the novice to hit the happy medium, it may be as well for him to know that the principal objection to having the polish too thin is that it will take a longer time—*i.e*, more work to get a good body on the wood. It will, however, be better to run the risk of this than to have the polish too thick. An experienced polisher would soon detect any fault in either direction by the way in which the polish works, but it cannot be expected that the novice should do so. He must, therefore, be on the look-out for any irregularities in the shape of lumps or ridges which he may see, and, with a little attention, he will have no difficulty in avoiding serious mishaps.

Now, instead of hurrying on with the work, let it stand for at least a day, carefully covered up from dust; and on examining it again the body will be found to have sunk, but to what extent will depend upon circumstances. Any way, even the beginner will not fail to notice that it presents an altered appearance from that which it had when it was put away. This is owing to the polish having sunk into the wood, more or less. To compensate for this sinking, the work must be bodied up as before, always remembering to use as little oil as possible. The work will again be laid aside, and the bodying process be repeated till no more seems to sink in, even if the work is laid aside for a few days. When this stage is reached the bodying may be considered complete, and the work ready for the first polishing operations. Before proceeding to consider these, I have, however, to make some general remarks, which will enable the learner to work with more chance of success than if he were left alone, and told to glaze or spirit off. How to do these operations must be left for a future article, and meanwhile the novice will do well to note the following hints.

The number of times the work will require to be bodied up depends almost entirely on circumstances; but even for the best work, and that which is intended to be as durable as it can be, it need rarely exceed four. Fine, close-grained woods will not require so many as the more open kinds, such as oak, ash, mahogany, etc. Any reasonable interval—that is, one of several days—may elapse between the different bodies, the great object of waiting being to let them sink as much as they will. If, for example, after having laid the work aside for a few days, the polish has not sunk at all, no object would be gained by giving it another body, and so on with future bodyings. Of course, it is very seldom that the first body is enough. All the same, only one body is often applied in the trade, where either price or the limited time within which a job must be finished will not allow of more, so that cabinet-makers and others who may wish to do a bit of polishing must not suppose the process cannot be hurried.

Still, imperfect bodying is not advisable, as it will not be long before the work will want "touching up." Of course, if a job is like certain oft-referred-to razors, "made to sell," one body, and that of the slightest, is quite sufficient—from the seller's, if not from the buyer's, point of view.

Between the bodyings, especially after the first and second, the surface should be rubbed down with the finest glass-paper, not to such an extent as to rub all the body off, but just enough to smooth it. It may here be remarked that the pumice powder referred to in a previous article is, when used in moderation, useful for working down inequalities of surface. Although papering has been stated to be necessary after the first and second bodies, it must not be supposed that it may not be done after any others if they require it, which, however, they should not if the work has been skilfully done. In fact, as we shall see later on, the final bodying up may almost be regarded as the beginning of the spiriting off.

Before beginning to work a fresh body on a previous one, it is just as well to wash the surface gently with a little lukewarm water, and not too much of it, in order to remove the grease and allow the rubber to work freely. The water must be thoroughly dried up before applying the rubber, and, as is often the case, the washing may be omitted. In moderation, however, it can never do harm, and is generally an advantage, even though not absolutely necessary. When any long interval has elapsed the washing should never be omitted, as, of course, dust—otherwise "matter in the wrong place"—will settle on the work, and should not be rubbed into the polish.

Professional polishers should be careful to see that their hands are clean, or free from the old polish, which is so often seen on them, when doing any bodying up. If they are covered with the old polish or shellac, bits are apt to flake off and destroy the purity of the new work. Of course, this remark applies equally to amateurs and novices, but their hands are not so likely to have old polish sticking to them. As polishing is not altogether clean work, this may be an appropriate place to say that any polish which sticks to the hands—as some is sure to—may be washed away with hot water and soda, or with methylated spirit.

There may be some risk of novices supposing that a thick body is desirable: the opposite is the case, for it should be as thin as it can be. It is not so much the quantity of body on the wood as its quality that is required, and the way in which it has been applied, with sufficient intervals between the various bodies to allow of sinkage.

Another important matter is to dry the rubbers well out—that is to say, work them on each body till they are dry, and do not be continually moistening them. By this means the film of shellac is kept as thin as possible.

On no account should a wet rubber—or, I may say, one wet or dry—be allowed to stand on a surface while it is being polished. The rubber must be kept moving, and should, if I may so express it, glide gradually on to the work, instead of being plumped down on it. In the initial stages of bodying, care in this respect is not so important as later on, when it is absolutely necessary. The same degree of caution should be used when lifting the rubber from the work.

If it can be said that one portion of a piece of work requires more attention than another, it is towards the edges. On the "take care of the pence and the pounds will take care of themselves" principle, it may be laid down as a rule for the guidance of the beginner, that if he takes care of his edges the rest of the surface will look after itself. The reason is that the edges are apt to be somewhat neglected, and the polish to be less there than elsewhere.

With the remark that the secret of a good durable polish depends primarily on a good body, and this, in its turn, on sufficient time having been allowed for sinkage, my remarks on this part of my subject must be closed.

## THE SAFETY BICYCLE: ITS PRACTICAL CONSTRUCTION, ETC.

BY A. S. P.

### Building the Wheels.

Component Parts of Wheels—Spokes—Wheel to be Built—Dividing out Rim—Finding Length of Spokes—Fitting Oil Cup—Wiring One Side of Wheel—Wiring the Other Side—Determining Position of Chain-Cog—Loose Cone—Bottom Brackets—Direct Spoke-Wheel, why Described.

Our first practical work will be the building of the wheels. The wheels consist of hubs, spokes, rims, and tires, and there are various kinds of each of these. With regard to hubs, we have them of solid steel casting all in one piece; again, we have them of steel and gun-metal in combination, the steel parts being the two caps in the ends, which are hardened for the wear of the balls, and in the case of the rear hub the chain cog-wheel is also of hardened steel.

Spokes are of various kinds: as direct, butted, laced, and tangent. Direct spokes are those in which the wire is all of one thickness, screwed at the end next the hub; the hub being bored for them direct towards the centre, they enter the hub about $\frac{1}{2}$ in. Butted spokes also enter the hub direct in the same way and to the same depth as the above, but the end of this spoke is thickened and screwed on this thick part. The spoke itself is usually No. 11 or 12, while the screw part at the end is No. 8. Common direct spokes usually snap just at the edge of the hub where the screwing has left off; it will, therefore, be apparent to anyone that a spoke thickened to nearly double at that part will be much stronger. I may mention that the Singer Company build nearly all their machines with butted spokes, and in all my experience in repairing their machines, I have hardly ever found a broken spoke. I have found numbers pulled right out of the hub, but never broken. Tangent spokes have their heads at the hub and the screwed ends at the rim, where nipples are used to tighten up the wheel. The hub flanges are made thin, and holes bored sideways for the spokes; the spokes are bent at the neck—that is, a little way behind the head—and passed through the flange towards the rim. Laced spokes again have two spokes in each length of wire; the flanges are made the same as the last, but the spokes have no heads whatever, they are simply laced through the flanges; the wire, being long enough for two spokes, is doubled in the middle, and the ends led away to the rim at more or less of a tangent; the ends are screwed and fitted with nipples as in the last case. Tangent and laced wheels have usually hollow rims, which allow the nipples to be sunk out of the way of the rubber tire. A wheel with a hollow rim is consequently dearer, the rim alone being four or five times dearer than an ordinary crescent rim.

The wheel we propose building for our Safety is of the simplest direct order with No. 10 spokes, headed at the rim. We will describe the building of one wheel, as the building of both is precisely the same. Say you have purchased a pair of hubs, tapped and plated ready for putting into your wheels. The rear hub should have not less than forty spoke-holes, and the front hub not less than thirty. A screw-plate should be provided to screw the spokes, same gauge as the hubs are tapped.

Say you purpose building the rear wheel. Find the number of holes in the hub, and

divide off the rim all round and equidistant for the same number of holes. Wheelmakers on a large scale have division rings for boring wheel rims any number of holes, but as our cycle-maker is not supposed to possess this appliance, he must measure off the rim with a pair of compasses. Take a piece of string and pass it round the hollow of the rim, and measure the exact length it takes to go round; reduce this length to inches, and divide by the number of spokes—say forty; the answer will be two, with a remainder; reduce the remainder to $\frac{1}{8}$ths and divide again, when you will get approximately the divisions of the spokes. Go round the rim in the hollow with the compasses or dividers, marking lightly with the points, first making a mark with a centre-punch to start from; count as you go round, and repeat the operation till the leg falls into the mark you started from; then centre-punch all the marks—forty—with the rim hanging on the nose of a high anvil, or across a leg vice when shut. Next bore with a drill one size larger than the spoke wire. If the boring is done with a lathe, let the rim rest on the lathe-bed at the right hand, and bore half the holes—that is, miss and take one—then turn the rim over and bore the other half; in this way the holes have an angle in the direction of the hub, and will appear somewhat ziz-zag on the inside of the rim. Care must be taken, however, to place the spokes in the proper holes when building the wheel. Having bored the rim, the next thing is to countersink the holes with a $\frac{1}{4}$ in. drill; this should be just sufficient to let the spoke head in flush.

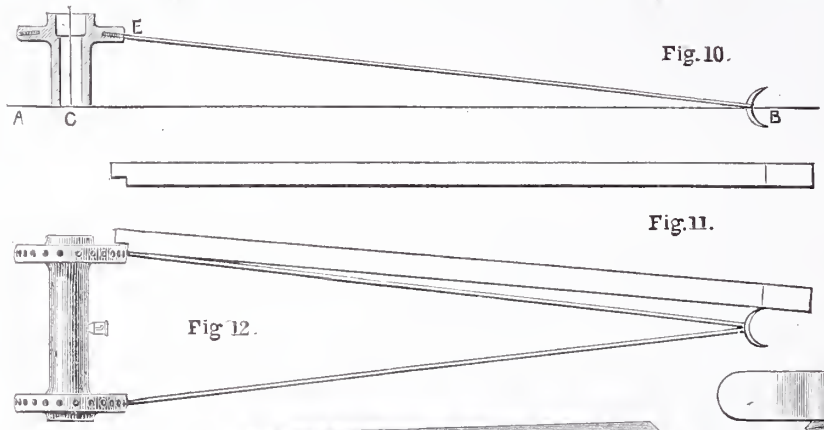

Fig. 10.

Fig. 11.

Fig. 12.

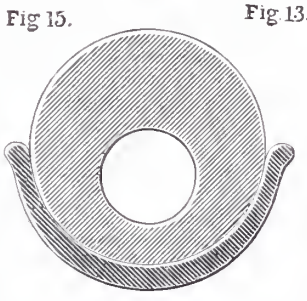

Fig. 15.

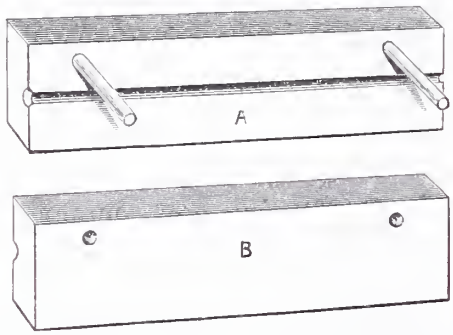

Fig. 13.

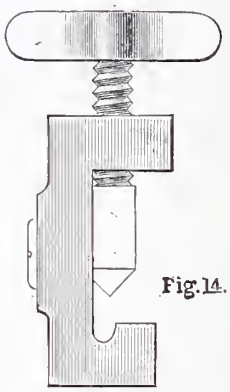

Fig. 14.

Fig. 10.—Mode of finding Length of Spokes (one-fourth size). Fig. 11.—Lath for truing Wheel (one-fourth size). Fig. 12.—Application of Lath (one-fourth size). Fig. 13.—Spoke Header (half size). Fig. 14.—Spoke Grip (full size). Fig. 15.—Cushion Tire (full size).

Now to find the true length of the spokes is an important matter, because if they are too long the wheel must come down again in order that they may be shortened. To find this true length, a drawing must be made, full size, similar to Fig. 10 here shown, which is one-fourth full size. Draw the line A B; on A B take a point C; at right angles to A B, at C, mark off half length of hub—that is, from centre of hub to the spoke-holes—and draw the half hub in section as shown: the spoke-holes should be drilled $\frac{3}{8}$ in. deep and tapped full length. Now measure exactly the diameter inside of the rim; take half this diameter, and mark the section of the crescent rim from C towards B. Next draw the line B E, which will be the length of the spoke, less the part that enters the flange, which should be not less than $\frac{1}{2}$ in. The spokes should all be cut exactly the same length, and screwed a little less than $\frac{1}{2}$ in.—say, $\frac{7}{16}$ in.; in screwing, find how many turns of the plate will do $\frac{7}{16}$ in., and give all the spokes the same number of turns. Now the holes in the hub flanges should have $\frac{1}{16}$ in. bored plain without screwing, and the full size of the wire, so that on building the wheel the screwed part will go out of sight in the flange. The spoke is in this way a little less liable to break off level with the flange, and when it does break off, it is at the end of the screwing and a little within the level of the flange, leaving a good recess for boring out the stump.

The next step before beginning to put up the wheel is to fit the oil cup, and leave it in its place. Now try a spoke in the hub, and screw it home; see that it is not too stiff to screw up, nor too easily screwed up; it should screw home with the spoke-grip without forcing, and it should not be so easy as to screw home with the fingers and without the use of the grip. Be sure that all the spoke-holes in the hub are properly cleaned out and properly tapped. Now to put the wheel together, place the rim on three or four bits of wood about 2 in. thick on the bench, stand the hub in the centre, and pass all the spokes for one side through, entering them in the hub a little way with the fingers only; of course, you will take and miss a hole in the rim, and notice at the same time the ziz-zag holes in the rim, and pass the wires through the holes that look upwards to the upper end of the hub. This, of course, will be at once clear to anyone performing the operation.

Having put in all the wires for one side, turn the wheel over and put in the other half. Now screw up the whole of the spokes with the grip till the screwed ends just disappear in the flange. Now to true the wheel, take a thin flat rod of metal, or a thin lath of wood, and make a notch at one end, as in Fig. 11; this notch rests against the flange, as in Fig. 12. Make a mark with a pencil on the lath where the sharp outer edge of the rim touches it; now apply the lath between the spokes all round the wheel on both sides, and observe where the edge of the rim falls within or without the pencil mark; this shows where to screw up and where to let down. This, I believe, is not exactly the method used by wheelmakers, but as I am a self-taught cycle-maker, I have to resort to my own methods, and I find the lath as above described to be very serviceable, as I have frequently put up wheels with it that ran dead true the first trial on their own spindle. I have, however, often found rims with a high edge and a low one, which destroys the true working of the lath as a gauge, and throws the hub out of centre—that is, gives the wheel more dish on one side than the other, which is to be avoided above all things. But assuming the rim to be truly made, and the hub flanges to be both the same diameter, if the rim all round on both sides touches the mark on the gauge, you may rely on the wheel running true on its spindle when tried; radially, it will be dead true, and if there is any side-wobble, touch it with a bit of chalk while revolving on its own spindle, and twang the spokes on the side with the chalk; if they sound tight let them down, say half a turn, and tighten up those on the opposite side, say half a turn. Try the wheel again, and any part, however little off the truth, will show with the chalk. It must be understood that a very slight tightening or slackening of a spoke makes a perceptible alteration on a wheel. One important thing to observe before the wheel can be said to be finished, is to see that all the spokes are of the same tension; this can readily be ascertained by twanging with the fingers. If they are all of one tension they will all give forth the same sound or note, being all of the same length.

Now, having finished this wheel ready for the tire, the other wheel is treated in exactly the same way, only you must see that the hub and rim are of the same diameter as the last, else you will have to make a new drawing to find the true length of spokes, or if using the same drawing, make allowance for the difference.

Now, with regard to the rear or driving wheel, you have got to determine on which side of the machine you will have the chain-cog, whether right or left; sometimes the make of the hub determines this, as the spindle having a fast and loose cone, the loose cone should always be on the *left* side of the wheel in running forward, for the reason that a loose cone is apt to turn on the spindle with the friction of the balls, especially when dry. Now, if the cone is on the right side, and turns on its spindle, the result is that it winds further *on* the spindle and jams in the hub, stopping the wheel; but if placed on the left side it turns on its spindle, winds off towards the fork side, and cannot jam the wheel, which is a lesser evil; of course, if the wheel is kept properly

adjusted and the outside nuts well up, the cone cannot run either way. Some makers of hubs, however, have both the cones loose; in this case the nuts must be kept well up, or the right cone will be sure to run in and jam the balls, stopping the wheel.

This rule with regard to the loose cone must be observed the same with the front wheel as with the back.

With regard to many of the bottom brackets in use the same rule holds good, as the pedal shaft has a fast and loose cone, with the chain-wheel keyed on immediately behind the fast cone. In this case the chain-wheel and chain should always be on the *right* side of the machine, which places the loose cone on the *left*, where it should be. I have handled many machines, however, where this rule was disregarded. In our bottom bracket, however, the two bearings are separate, being the same as those used on an ordinary bicycle, consequently we can fix our chain-wheel on either side.

I have, in this paper, described a plain direct spoke wheel on account of the difficulty of building one with butted spokes in the absence of a spoke heading machine, which costs between £4 and £5. A butted spoke being No. 14, and the butt end No. 8, the rim is bored with a No. 13 drill, so it will be readily seen the butted end will not pass through the rim; for this reason butted spokes have no heads, and are passed through the rim from the inside and a head worked on after the spoke is in the rim, hence the need of a heading machine. In the absence of a heading machine, I use a very simple contrivance which does the work fairly well. It is illustrated in Fig. 13, A, B, and consists of two steel plates, 4 in. long, 2 in. broad, and ½ in. thick. Plate A has two ⅜ in. round steel pins fixed into it; plate B has two holes to receive these pins, and the two plates when shut are flush all round with each other. Along the centre of both plates a shallow V-shaped groove is made, both grooves together being a little less than the thickness of a spoke. When the two plates are firmly caught together, a countersink is made at one end where the grooves terminate; this counter-sink is the recess to form the spoke head (see A in Fig. 13). To use this tool, the spoke is caught between the two plates in the grooves, about $\frac{3}{16}$ in. protruding beyond the plates at the countersink end. In this position it is caught in a strong vice, and the head formed by hammering the projection into the counter-sink; of course, the spoke has been passed previously through the rim. In building a new wheel, all the spokes would be cut the proper length, butt ends screwed, then passed through the rim and headed, after which the wheel would be built as described in the carlier part of this chapter. The spoke grip referred to in this chapter is illustrated in Fig. 14, and may be bought for 1s. 6d. Before closing this paper, I deem it advisable to say a word regarding cushion tires, which are the rage just now, it being just possible that our cycle builder may not be content with the ¾ in. crescent rim and solid tire herein described. If he purposes having a cushioned-tire machine, the tire should not be less than 1¼ in. diameter. A tire of that sort is shown in Fig. 15, with a section of the rim used, or ought to be used, with it, the edges being turned out and blunted or beaded to prevent cutting the rubber. The hole in this tire is ½ in., and, as will be noticed, is not central, but a little nearer the rim. Rims of this sort can be had, as well as hollow rims, formed on the rubber side in the same way, of Thomas Warwick's make.

It must be borne in mind that a 1¼ in. tire requires a wider fork to let it pass through, also a broader spoon for the break, as well as broader mud-guards. Our next work in cycle building will be at the lathe and fitter's vice.

## AN IMPROVED PIN-STOP BENCH-BLOCK.

BY J. BLACKMORE WILLIAMS.

Those workmen familiar with the common work-bench used by joiners, cabinet-makers, etc., are, I venture to state, well aware of the fact that the present bench-block mostly in use consumes a vast amount of time in adjusting, and the amount of labour required in, say, a year's time, where there are a number of workmen employed in shops and other places, is something enormous, to say nothing of the constant change of position, as the workman has usually to go round the corner of his bench to knock the block into the position he desires. The bench I use is for convenience pushed up against a wall, from which is suspended a woodrack, and in adjusting my bench-block I invariably experienced a great difficulty, which I remedied in the following manner:—

I sawed out of the end of the bench a piece, 10 in. by 2 in., and cut from the screw to the end of the bench-board on a slant, as shown in Fig. 1. I then procured an iron plate, perforated with small holes at intervals of ½ in., and grooved at the sides (as shown in plan and section at A and B, Fig. 3) for the reception of another plate, 2½ in. by 2 in., as shown at F. On to the latter plate, which

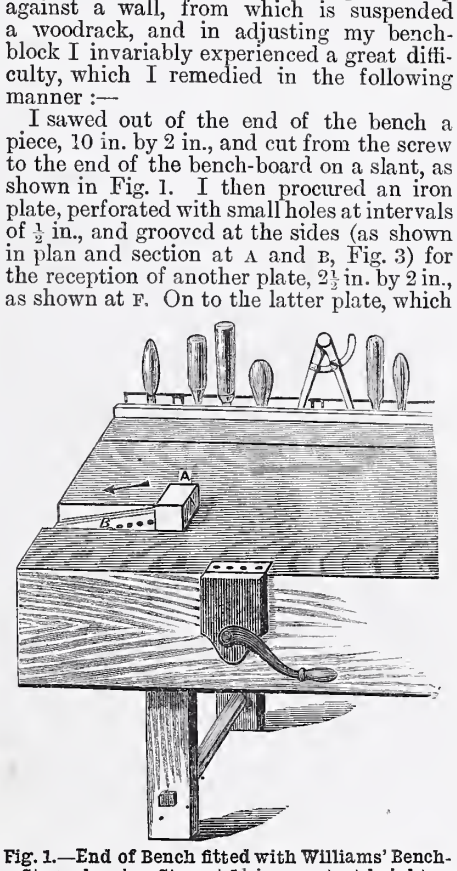

Fig. 1.—End of Bench fitted with Williams' Bench-Stop, showing Stop at 1½ in. greatest height.

was ¼ in. in thickness, I screwed from the underside of the plate my pin-stop bench-block, which must be cut on the level at the bottom, and so arranged for height that when it reaches the end of the bench, as in Fig. 2, it is perfectly level with the face of the bench. Fig. 1 will clearly show the reader the appearance of the block when adjusted, A being the bench-block, and B the bevelled groove, perforated with holes for the reception of the stop-pin, as shown at C in Fig. 3. At D is shown the 2½ in. by 2 in. plate with screw-holes, for fastening the wood bench-block, and E shows the bench-block when screwed on to the plate. At F is shown the bench-block complete. A and B, in Fig. 3, illustrate the permanent plate, B showing the manner in which the grooves are formed for securely holding the bench-block. The workman will readily see from the design the manner in which the block is raised or lowered by pushing it along the permanent plate; and on getting the desired height, he drops the stop-pin into one of the holes nearest the back of the bench-block. Some objection may be raised by workmen on the ground that when the block is at the end of the bench there is a cavity into which, say, an

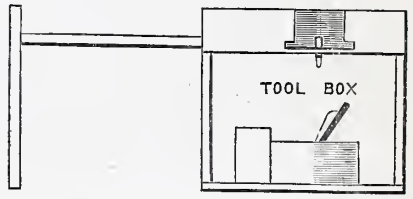

Fig. 2.—End Section of Bench, showing Pin-Stop Block at lowest height.

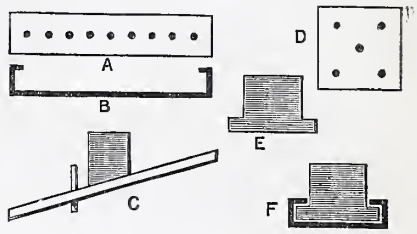

Fig. 3.—Parts of Pin-Stop Block—A, Iron Plate pierced for Pin in Plan; B, Plate in Section; C, Pin and Block.

inch board, in being shot, would fall in; but he will readily remedy this by letting in a slot-piece, fitted level with the face of the bench. Of this fact, there is no doubt that those workmen who adopt this inexpensive improvement will not only save a vast amount of time, but they will be able to adjust it without moving from the screw. I had at first thought to arrange a slot movement, but thinking of the quantity of sawdust which would tend to choke the cogs, I decided on the pin-stop, which leaves the permanent plate clear, and may be fastened to the bench by means of a small chain.

## ENGINE AND BOILER MANAGEMENT.

BY M. POWIS BALE, M.INST.M.E., A.M.INST.C.E.,

*Author of "A Handbook for Steam Users," "Wood-working Machinery," "Stone-working Machinery," "Pumps and Pumping," etc.*

### Rules for Engine Drivers and Boiler Attendants.

Filling Boiler—Examining Water-Gauge and Test-Cocks — Cleaning Tubes — Lighting Fire—Examining Safety-Valves—Lubrication, etc.—Examining Bearings—Raising Steam Slowly—Regular Admission of Feed-Water—Examining Height of Water in Boiler — Starting Engine — Surplus of Steam—Testing Safety-Valves and Pressure-Gauges—How to Test Pump—In Case of Low Water—In Case of Safety-Valves Sticking—Priming—Examining and Testing Steam Exhaust.

Owing to the multiplicity of types of engines and boilers in use, it is difficult to draw up a code of rules in which the wording will apply equally well in all cases. The *principles*, however, embodied in the following rules may be generally applied,

although the phraseology may sometimes require slight modification.

1. *Filling the Boiler.*—Fill the boiler with water till it rises to the mark on the gauge which shows the water line. If there is no water line marked, fill till the gauge glass is about three-quarters full.

2. *Examine Water-Gauge and Test-Cocks.*—Open all the water-gauge and test-cocks, and see that they are in order. If the water does not enter the gauge glass freely, it must be unscrewed and a piece of wire passed through the openings in the boiler.

3. *Cleaning Tubes, etc.*—Remove all soot from the tubes, and clear the fire-bars and ash-pit of clinkers and ashes. If the flues are dirty, have them swept.

4. *Lighting the Fire.*—Light the fire, which should be kept bright and even, and of a thickness of about 4 in. to 6 in. in tubular boilers, and from 9 in. to 12 in. in Cornish or Lancashire boilers, except when there is a surplus of steam, when a thicker fire may be used. The thickness of the fire should be regulated by the nature of the fuel. Should the draught be bad from dampness, direction of wind, or other cause, a temporary artificial draught may be made by lighting some shavings in the smoke-box or chimney.

5. *Examine Safety-Valves.*—As the fire burns up examine the safety-valve, and see that it moves freely in its seat. Examine float or low-water alarm if one is fitted.

6. *Lubrication, etc.*—Fill the lubricators. A little fine powdered plumbago or asbestos may be added with advantage, especially to the cylinder lubricator. The use of the best quality of oil or grease is to be recommended. What is required is a neutral grease that will not develop free or fatty acids under the action of steam. Its melting point should be low, so that it will liquefy with a small amount of heat, and yet it should retain sufficient body, that it will not readily run from the bearing surfaces. Lubricate piston rod and guides. Examine eccentric, and see that the key is tight and the lead of the valve has not been accidentally altered.

7. *Examine the Bearings.*—Examine systematically and screw up the bearings of the engine, not too tightly; this is best done, if required, immediately after finishing work for the day, as they are then expanded from the friction of working and are in their running condition. If bearings are tightened in the morning before commencing work, which is usually the plan, they are cold, and therefore contracted. If a bearing get hot, cool with water and scrape off all scored or rough places; if it knock in working, let the faces of the bearing be slightly closer together. Lubricate well with a mixture of grease or oil and powdered plumbago, say three of grease to one of plumbago. If the bearing be large and subject to great strain or pressure, the proportion of plumbago may be increased. Replenish all lubricators before starting work, and guard all bearings as much as possible from dust. If there is undue friction on the bearings, particles of metal will be found in the oil after using if it is spread on white paper.

8. *Raise Steam Slowly.*—Always raise steam slowly and avoid forcing the fire, as this causes uneven expansion and strains and damages the seams and boiler plates. Keep an even pressure of steam, but not one that has to blow to waste through the safety-valve.

9. *Regular Admission of Feed-Water.*—Hot feed-water is in every way to be preferred to cold; but if cold is used, do not admit it into the boiler in large quantities at a time. Keep the pump working regularly, but with the admission valve only partly open. We recommend the use of a feed-water heater, but if one is not fitted, direct the exhaust steam into the water-tank, say a quarter of an hour after starting, as by that time any accumulated grease from the cylinder may have blown away.

10. *Examine Height of Water in Boiler.*—Examine height of water frequently during the day, and try gauge and test-cocks and float. Blow-out and scum taps should be opened once a day at least, oftener if the water is bad. Be sure that the float is acting properly, as it is apt to stick, especially if of very light construction. The water-level in Cornish or Lancashire boilers above the surface of the flue should never be below 4 in. in depth under any circumstances, and a working level of about 9 in. will generally be found most suitable. In finishing work at night leave a full supply of water, in case of leakage or frost.

11. *Starting the Engine.* — Supposing steam to be up to the working pressure, the safety-valve having been tested at intermediate points, turn the fly-wheel of the engine till the crank shaft is at half-centre. Before starting, let the engine cylinder be thoroughly warmed; this is especially advisable with large engines or in frosty weather. Now open the cylinder cocks and turn on the starting lever or valve gradually to about one-third of its traverse. Steam now enters the cylinder, and the engine is set in motion. When no more water is expelled from the cylinder, close the cocks. See that there is no leakage of steam from the piston-rod packings or any of the joints. Allow the bearings of a new engine to be a little slack for a time. Never start or stop an engine suddenly.

12. *Surplus of Steam.*—When there is a surplus of steam, close the damper, rake the fire-bars so as to admit the air from below, open the ashpan lid if there is one, and keep the furnace door closed. (N.B.—The author recommends, wherever possible, the use of a damper worked by steam automatically, as it is certain in its action and independent of the boiler attendant. It can be arranged to act at any desired pressure of steam, and effects an appreciable saving in fuel. It is important, whatever form of automatic damper is used, that it is arranged with a sensitive action. This may be secured by hanging the damper on a steel-pointed screw pin, and making the working parts with steel centres and V edges. This will allow the damper to open or close with rapidity when the desired pressure of steam is reached.) Where the work varies very much, automatic expansion gear should be fitted.

13. *Testing Safety-Valves and Pressure-Gauges.*—Test the safety-valve at least twice a day; if about $\frac{1}{8}$ in. to $\frac{1}{4}$ in. of space is shown between the valve and its seat for the escape of steam, this is usually sufficient if the valve is of proper area for the boiler, but some valves are arranged to lift less than this. Pressure-gauges should also be occasionally tested by shutting off the steam and letting the pointer run back to zero; for this purpose the cock to the gauge should be arranged to open to the atmosphere when shut off from the boiler. Check also the safety-valve against the pressure-gauge by altering the former to blow off at whatever pressure is at that time shown on the pressure-gauge. If they do not agree, have the gauge tested by a standard one. See that the figures on the pressure-gauge are large and plainly marked, so that they may easily be read at some distance away. It is also best to distinguish the average or safe working pressure of the boiler by a red line on the gauge; this can readily be reduced as the boiler deteriorates. If the pressure-gauge shows the blowing-off point, and the safety-valve is found to be stuck or inoperative from any cause, start the feed-pump, close the damper, and open the furnace door. Start the engine should it be standing, and let the fire out or draw it when the pressure is reduced. Never under any circumstances wedge down or overweight a safety-valve, and "wire-drawing" the steam should not be resorted to. Should the valve leak at all, have it reground at once and made perfectly steam-tight.

14. *How to Test the Pump.*—Test the pump occasionally by opening the waste-tap; if no water is expelled the pump is not working, either from there not being a vacuum, the packing or joints being out of order, the valves choked with dirt, or the pump hot. Before taking it to pieces place your hand tightly on the end of the waste-pipe, allowing the air to be discharged from the pump by the inward stroke of the plunger, but not allowing any air to re-enter during the outward stroke. If this has the desired effect in setting the pump to work, close the waste-tap, and the water will be forced into the boiler. If the pump gets hot, pour cold water on it. If hot water continually issues from the waste-cock, the probability is the check-valve nearest the boiler is choked. In this case the steam must be blown off and the fire put out, the valve-box cover must be taken off, and the dirt or obstruction that prevents the valve acting removed. If the suction or delivery valves are choked, hot water will not pass through the waste-cock; these valves may be examined when the engine is working, but should the defect not even then be discovered, the suction-valves, delivery-valves, and the packing of the plunger must be examined and the packing renewed, as the pump is probably drawing air; screw up and clean the union nut of the suction pipe, and make another trial. Occasionally a valve that has stuck may be released by a few sharp blows of a hammer on the outside of the clack cover. If a pump plunger is worn it will not act, at any rate satisfactorily, and should be seen to. In case it is necessary to take the pump to pieces, should there be no check-valve fitted or it be choked, be sure that the water stop-valve is closed, or the boiler may be drained of water and an accident occur. If a valve has too much lift it is apt to stick, and should, therefore, be adjusted periodically as it wears. Feed-pipes should in all cases be of ample size, owing to their liability to fur up. Bends in the suction or delivery pipes should be avoided. Take every precaution to prevent sand or grit getting into the feed-water.

15. *In case of Low Water.*—In case of low water—that is, where none shows in the gauge-glass or lower test-cock—draw the fire immediately; but, should the furnace crown be red-hot, cover the fire with earth or wet ashes so as to smother it. Close the damper and ash-pit door and open the furnace door. If the boiler is very hot, and the heat is likely to be much intensified by drawing the fires, it would be well to smother them instead of drawing, but judgment should be used, as no fixed rule can be laid down. If a little water is shown by the

lower test-cock, the feed may be turned on.* The Manchester Steam Users' Association say in this connection: "Shortness of water generally arises from neglect of the boiler attendant, and ought not to occur. It is by no means easy to give precise instructions as to what should be done to put things right when shortness of water has occurred, so as to meet every case. Drawing the fires when the water is out of sight must always be a matter of more or less risk, as there is a difficulty in determining how far and for how long a time the furnace crowns have been laid bare. If it is known that the water has only just passed out of sight, say from the sticking fast of the blow-out tap when attempting to shut it, the fires may be drawn with safety. But if an empty gauge-glass has been mistaken for a full one, and the boiler has been worked on in this state for some time, the case will be different. Again, there would be more risk in drawing the fires from a plain furnace tube, or from one made of ordinary plates, than from one strengthened with encircling rings, and made of ductile steel or of iron equal to Lowmoor or Bowling. Thus, it will be seen, it is difficult to give precise instructions to suit all circumstances. A fire may be safely drawn in one case and not in another."

16. *In case of Safety-Valves Sticking.*—Should the safety-valve stick from any cause, and the pressure of steam be near the blowing-off point, (1) keep the engine running, and if steam is taken off for any purpose, open the valve; (2) start the feed-pump; (3) close the dampers; (4) open the furnace door; (5) if thought necessary, damp down or choke the fire with wet ashes.

17. *Priming.*—In case of priming, close the throttle-valve for a short time, find the true level of the water, and open the cylinder-cocks. If the water level is correct, blow off a little occasionally and add fresh water, but not too much at a time. Check the draught to the boiler also, and damp the fire somewhat. See that the feed-water is not dirty or greasy. In boilers where the steam space is small, great regularity of firing and water supply is necessary. If the priming is violent, stop the engine. Open the cylinder-cocks occasionally. Some of the compounds sold to remove incrustation will cause priming. Priming may also be caused by bad circulation, by an excess of steam being drawn from the boiler, or by the introduction of oatmeal or similar substances with the object of stopping leaks. In case of violent priming, the gauge-cocks will discharge a mixture of steam and water instead of plain water. It should not be attempted to stop priming by the introduction of oils, as is sometimes done, as most of these develop fatty acids, which are often highly injurious to the boiler, and by mixing with the lime or other incrustation prevent a proper contact of the water with the boiler-plates; there is therefore a much greater tendency to burn.

18. *Examine and Test Steam Exhaust.*—An experienced and careful attendant can gather no little information as to the working condition of his engine by attentively listening to the pulsation of the steam exhaust. If the piston, slide-valve, and passages are in good order, the sound of the exhaust will be regular and decisive. If the piston is out of order, or the rings broken or worn, the pulsation will be prolonged, accompanied by a rumbling, groaning noise. If the pulsation is prolonged, with a wheezing noise, probably something is wrong with the slide-valve, and it may require adjusting or re-bedding. In either of these cases steam is wasting past the piston or slide-valve, and should receive immediate attention. To test for a leaky piston, put engine on dead centre and listen to the exhaust; should there be an escape of steam the piston or rings require attention, or the cylinder may want re-boring. The piston should be tried at both ends of the cylinder. If there is a simultaneous discharge of steam through the pet-cocks at both ends of the cylinder, you may be sure the piston is leaky. To test for leaky slide-valve, place engine a little over half-stroke and turn on steam; if there is a rush of steam through the exhaust the valve leaks. Steam may also escape directly into the exhaust-pipe through a leaky joint. A leaky piston may be caused through the engine being out of line

## ARTISTIC LITHOGRAPHY.

BY MISS ADA J. ABRAHAM.

TECHNICAL WORK — MORE ABOUT STIPPLING.

TINTS IN LINES AND STARS—TINTS SHADED UP FROM SOLID—BALL IN STIPPLE WORK—EXAMPLES OF RULING—TEMPERATURE OF STONE — FINGER-MARKS.

RECURRING to the subject of stippling, it may be said that Figs. 10 and 11 give very fair examples of shaded stipple tints, worked in stars, and Fig. 12 of tints worked in lines. It must be observed that the darker the tint, the closer and larger the dots, and the lighter the tint, the finer and more open the dots are, this being an infallible rule in stipple work. Fig. 13 is another example of shaded lines, which the student would do well to copy.

In a shaded tint where the darkest part is perfectly solid (Figs. 14 and 15) the student will find it impossible to shade it to a light tint without filling in; but the better the dots are laid in in the first instance, the less work is subsequently required. In an unimportant part of the picture it is not necessary to spend so much time in making a perfectly executed tint of regular dots, as long as the necessary effect of an even tint is produced. Fig. 15 is a specimen of what would be required for a good piece of shading, such as that on a face, an arm, etc., and Fig. 16 that for an unimportant part of the picture, such as a shadow thrown by a table. When the student is able to do a ball like that which is shown in Fig. 17, he may consider he has crossed the *pons asinorum* of stipple work.

Only two examples of line work are given (Figs. 18 and 19), as every different subject requires a different treatment; and here the student's artistic knowledge stands him in good stead, as he will then understand not to put the same kind of work in drawing a vase as if he were drawing a carpet.

The above examples of tinting are merely a few specimens of what is required in lithographic drawing with regard to stipple work, as each student can only gain by his

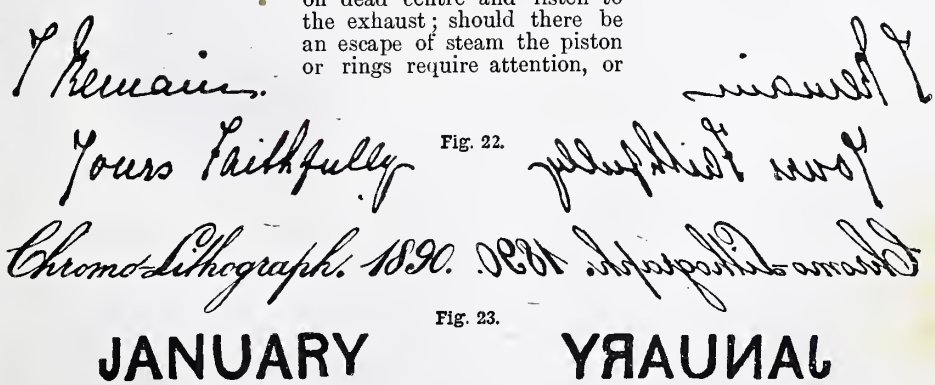

Fig. 22.

Fig. 23.

Figs. 22, 23.—Examples of Writing.

own experience the various styles and textures necessary for different kinds of work. It being found impossible to give many specimens of ruling, using the compass, lines drawn with the brush, writing, etc., Figs. 20, 21, 22, 23 must suffice at present as a slight guide to the student as to what will be required from him in that direction; but he must perfectly understand how necessary it is to practise with the different instruments before attempting any practical work. For instance, he will find the bow compass slip all over the stone, until he obtains full control in holding it firmly on one point, allowing the pen to glide easily over the stone; the same applies to the ruling pen, as it must be allowed to glide over, and not be pressed on the stone; and it will not be out of place here to observe, that it is easier to join straight lines to circles than *vice versâ*. The brush will be sure to make a thicker line than is required, until the student obtains a touch delicate enough only to work on the point.

It will perhaps be thought that lithography is made out to be more difficult than it really is, but the reader must not forget that good work is not easy to accomplish, and cannot be done without a certain amount of patience and perseverance, and if the artist understands what is required of him in starting lithography, he will not be as disappointed as if he thinks he can learn it in six, or even twelve, months.

To proceed with the work, the artist must remember never to work on a very cold stone; it should be warmed at the fire before beginning work for the day, especially if it has been kept in a damp cellar, and the back should be put next the fire in preference to the front, as the heat will then draw the dampness away from the drawing surface. Should the stone be too large to move with convenience, heat a flat piece of iron and hold it close over the stone for a short time, taking care not to touch it.

Finger-marks on the stone are apt to roll up in printing, and may appear as black smears—in fact, leaning against the stone might make it greasy, and so have the same effect as if it had been drawn in ink.

In practising tinting with the pen, it is not necessary for the student to confine himself entirely to one style of work in any one subject, such as an arm or hand, for example. It is, in fact, necessary, at times, to blend dots in lines with those in stars. For instance, when drawing an arm, in order to give force

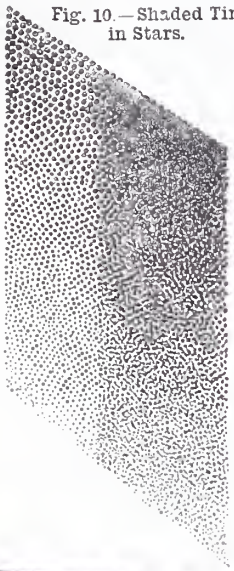

Fig. 10.—Shaded Tint in Stars.

Fig. 18.—Specimen of Line Work.

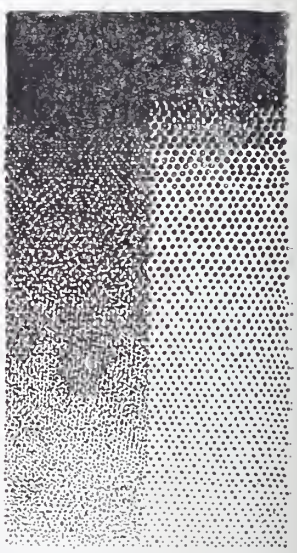

Fig. 15.

o the drawing, as there is no decided outine, about three or four rows of dots in ines should be drawn down the edge, the ast row being finer than the others to give oftness and roundness to the figure; this vould be gradually worked off into stars owards the high lights, thus giving effecive drawing and shading in the one tint by he judicious management of the dots. In he same way in drawing a face, parts, such s those under the eyebrows, round the ving of the nose, the mouth and around t, near the ear, etc., would all be drawn vith the dots in lines, in the various direcions of the features; whereas the forehead, heeks, neck, etc., would be drawn in stars, hus giving a certain amount of modelling, nd helping the shading by giving much nore character to the subject than if a flat int were laid equally all over the drawing nd then filled in, for however well it may e modelled, the drawing would always ave a flat appearance—insipid, if I may use hat expression, and without character.

In filling in a tint, the student should not ook as closely at his work as when he ays in the dots in the first nstance, for if he does so, and hen regards it from a distance f about a couple of feet, he vill, no doubt, be very surrised to see what a patchy ppearance his drawing has. his is owing to the fact that n looking so closely at his work e fails to take in the general ffect; so if he looks closely at is work, and is careful in laying in the dots clearly and venly, and then fills it in from little distance, he cannot fail o get a clear drawing and venness of texture. It is not bad plan to sit down to lay n the dots and stand up to inish it.

With regard to the student's osition whilst at work, it is etter for him to sit facing the ight for all such work as writngs, maps, etc.—in fact, that lass of work which appertains o the draughtsman; but for rtistic drawings and colour work, nothing quals a side or, if possible, a top light. Let he novice take any ordinary water-colour ketch, and, facing the light, look down pon it, and afterwards place it so that he ooks at it from a side light, he cannot fail o see the difference that I mean. Naturally, his would apply the same to copying from t on stone, for it would be a great mistake o sit facing the light to work on the stone, nd, having the copy on the right or left, be ontinually turning round to look at it. It s surprising what a different effect the lrawing has when held at a different angle o the stone on which one is working. Certainly, the best way is to have the drawng in front of you; but should this be impracticable through want of space, etc., the rtist should, at any rate, endeavour to so rrange his copy that he looks at it as nearly as possible full face—*i.e.*, at right ngles, and not sideways. Some people cannot face the daylight when at work, and many maintain that it is actually injurious o the eyes to sit with the face to the light day after day, such as regular office work ntails. Here is a case of "what is one man's meat," etc. On the whole, the best dvice I can give is this—secure the best vailable light for your work with the least ossible injury to the eyes.

## A HANGING MEDICINE CUPBOARD.

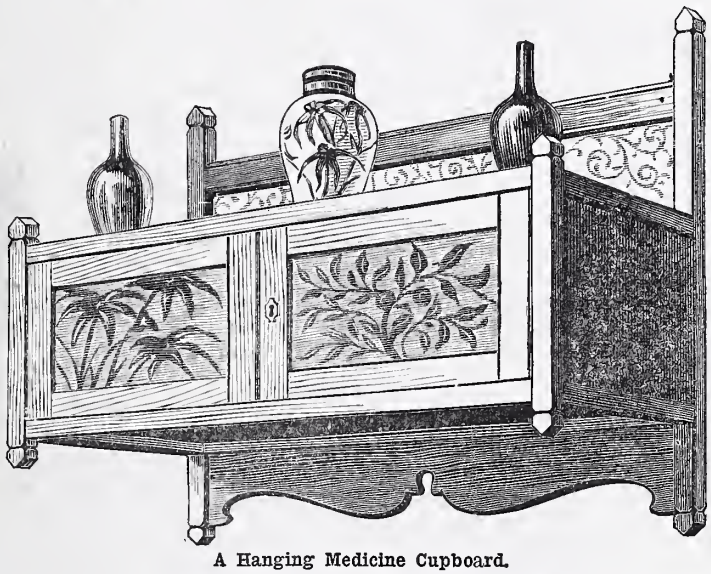
BY B. R. CONDER.

Alternative Use for Cupboard—Dimensions—Construction of Framework — Doors — Decoration of Panels—Finishing—Cost of Material.

Small cupboards are so generally used in the present day in rooms of all kinds, and are so generally useful, that many may like to know how they may be easily made.

The small article here described, though primarily intended for a medicine cupboard, can be easily adapted to answer a different purpose. By substituting glass for wooden panels to the doors, and lining the interior with some suitable decorative material, such as lincrusta, Japanese paper, or plush, it might be converted into a handy receptacle for a few small curios and knick-knacks.

Its dimensions are as follows:—Width, 2 ft.; depth, 8 in.; height of cupboard proper, 10 in.; extreme height in front (*i.e.*, of uprights), 12½ in.; at back, 22 in. This is a handy size; but it can, of course, be altered to meet individual requirements.



A Hanging Medicine Cupboard.

The framework of the cupboard, which must first be prepared, consists of twelve strips of wood ⅞ in. square, four being upright and eight horizontal. They are mortised and tenoned together; the tenons, of course, being cut in the horizontal rails, and the mortises in the uprights. It will be obvious that these joints must be carried only about ½ in. through the uprights, and that, therefore, the horizontal rails must be about ¾ in. shorter than the extreme width and depth of the cupboard respectively; also that the joints must be cut as near the outer edges of rails and uprights as practicable. It will be necessary at this stage, and from time to time as the various parts are got ready, to fit the work together, and test it with the square.

Next prepare the cross-ties, shown in the drawing, one above, the other below, the cupboard at the back. They are to be let into the back uprights from behind, the joint used being the lap-dovetail, the construction of which has been clearly explained in Work, Vol. II., page 118.

The upper tie is 1½ in. wide and ⅞ in. thick, which is also the thickness of the uprights to which it has to be joined; these joints must therefore be halved. The height of this piece above the cupboard is sufficiently indicated by the drawing, and is not material; a plain beading is cut on its front edges. A very passable beading may be easily contrived with a little care and patience, by those who do not possess beading planes or router, with a cutting gauge, chisel, and glass-paper. The cross-tie below the cupboard is ½ in. thick, or less, and 3 in. wide in its widest part; its lower edge may be cut to some such shape as shown with a frame saw, or failing that, with a keyhole saw. The panels forming the sides of the cupboard may now be got ready. They are ¼ in. thick, and fit in grooves cut in the side rails and uprights. The top and bottom next claim attention; they need not be more than ¼ in. thick, unless destined to carry more weight than usually falls to the lot of such a small cupboard.

The top, which forms a handy shelf for the display of a few small ornaments, is lap-dovetailed into the upper edges of the top side rails. The bottom rests in rebates cut on the lower front and back rails, and is secured to them by a few small screws or brads when finally fitted.

The ends of the uprights may now be cut as shown, or otherwise finished off, the various parts finally fitted together and glued up, and a thin back affixed. The back extends from the lower rail to the upper cross-tie, and thus the upper part of it forms a narrow panel above the cupboard. A small beading is fitted round the inside edges of the front, and allowance must be made for this in setting out the doors. The styles and rails of the doors are ⅞ in. thick and 1½ in. wide, with the exception of the falling styles, which overlap, and are therefore ⅝ in. wider. A rebate of that width is cut on the inner surface of the right-hand and the outer surface of the left-hand style, to allow for their overlapping and shutting level. A small beading is cut on the lock style.

The door frames are mortised together in orthodox manner, but might be halved and screwed from the inside by any preferring that method. They must be either grooved or rebated for the panels, which are ¼ in. thick.

In small doors of this kind, rebating the styles and rails and securing the panels by beadings, or simply by brads, is, perhaps, the better plan, as it permits of the easy removal of the panels at any subsequent time without injury to the framing. The appearance of the cupboard will be much improved if the panels are suitably decorated.

One very simple and effective method of doing this is to cover them with Japanese gold leather paper. This is an expensive material if bought in the ordinary way—by the piece; but one of Liberty's 1s. 6d. remnant bundles will afford sufficient for decorating several small pieces of furniture. This wrinkle I got from an early number of Work, and take this opportunity of acknowledging my indebtedness to the writer of the article in which it appeared.

A stop will be necessary to prevent the doors opening inwards, also some kind of a bolt to keep the left-hand door closed. A

very small block of wood glued or screwed to the front of the bottom, where the doors meet, acts as a stop; and a very efficient substitute for a bolt is provided by fastening a small wooden button, with a screw upon which it can be turned readily, but not loosely, to the inner surface of the falling style or top rail of the left door, about ½ in. from the top. When the door is closed this outton is turned, so that the part of it then uppermost comes behind the top front rail of the cupboard, and the door cannot then be opened until it is turned down.

All now left to be done is to cut the key-hole, fix the lock, and hang the doors, and the cupboard is complete. I have said nothing about the wood to be used, as almost any kind would do, provided it be sound and dry. As a hint to those who desire to produce their work as cheaply as possible, without sacrificing good effect, I may add, that a cupboard I made for myself of good sound deal and enamel painted looks very well, and cost for material, including a good lock, less than 2s. 6d.

## MEANS, MODES, AND METHODS.

### How to tie a Painting Brush.

Many people who need a paint-brush, buy one, and find that it is too long and limp to work well. It needs tying. This is a difficulty to the inexperienced, and here is a "method" of tying a brush.

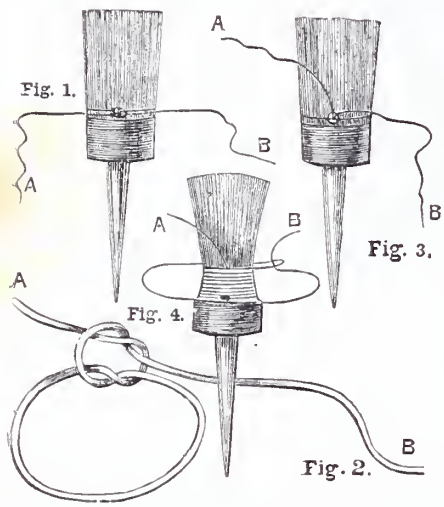


**Fig. 1.—Commencement of Process. Fig. 2.—The Knot used to secure String. Fig. 3.—Mode of laying Cord on starting to bind. Fig. 4.—Completion.**

First tie a piece of stout twine (twine like that used for Macramé work will do well) round the brush, leaving 6 in. or 7 in. at one end, marked A in the sketch. Fig. 1 shows the first tie. Fig. 2 shows the form of knot used. The end A should be made to lie along the hair of the brush, and the string should be coiled round it and the hair of the brush as many times as necessary. When enough has been wound around, the cord marked B may be bent back, drawn close, and a half knot made opposite the first knot. Both cords may now be fixed with small tacks to the stock or the handle of the brush, and the superfluous string cut off. The string need not be bound very tightly, for either paint or water will make it sufficiently tight for the purpose for which it is intended. At any time part of the string can be removed. B. A. B.

## OUR GUIDE TO GOOD THINGS.

**** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 37.—Practical Blacksmithing.

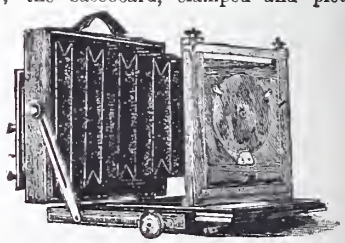
Some little time ago it fell to my lot to notice Vol. III. of a capital *vade mecum*, entitled, "Practical Blacksmithing," by Mr. M. T. Richardson, comprised in four volumes, and covering nearly the whole range of blacksmithing, from the most ordinary operation to some of the most complex forgings. It is an American publication, but is sold in London by Messrs. Kegan Paul, Trench, Trübner & Co., Limited, Paternoster Square, London, E.C., who will, I am sure, readily give any applicant information as to the price at which they supply it. Vol. I. gives the early history of the trade, with shop plans and methods of constructing chimneys and forges. Vol. II. is devoted to a description and illustration of the tools and appliances in use. Vol. III. dealt with such tools as had not been considered in Vol. II., and contained a description of a great variety of jobs of work. In Vol. IV. the last-named topic has been continued and completed, and considerable space has been devoted to the subjects of cutting, bending, welding, and setting tires, setting axles, resetting old springs, the tempering of tools, bolts, nuts, etc., and the working and welding of steel. The last chapter comprises a set of tables, giving the weights and sizes of various articles in steel and iron, used for the most part by carriage and waggon builders, and therefore of importance to all who are engaged in this particular trade.

### 38.—Photographine.

Some readers may like to try the compound known as "Photographine," which is prepared and supplied by Mr. J. Pawsey, 8, Catherine Terrace, Seven Sisters Road, Tottenham, N. He claims that by its use plates may be cleared without injury to the film years after being fixed, and that, by reason of its cheapness, it is economical in its use. Further, he claims that it hardens the film as well as clears the negative, and that this is a most desirable feature in the production of good pictures. Plates, too, that are over-developed speedily assume their proper density on being brought, it is said, in contact with this bath. The following developer is suggested for use:—For the soda solution, 3½ oz. of soda, 1 oz. of glycerine, and 1 quart of boiling water. For the pyro solution, 1 oz. of pyrogallic acid, 20 drops of nitric acid, and 8 oz. of water. For use, take 1 oz. of water, to which has been added 24 drops of the pyro solution; then add 1 oz. of the soda solution. After developing, well wash the negative in clean water, and then place it in the Photographine bath compound thus: 1 oz. of photographine, 4 oz. of boiling water, and ½ oz. of loaf sugar. This bath should be mixed twelve hours before being used. This solution will keep any length of time, but should be renewed as soon as it has lost its original colour—by turning black. *Caution.*—"Negatives treated thus print quicker and sharper than those treated in the ordinary way." The preparation is sold in 1 oz. packets, 4½d. post free, or in 1 lb. boxes at 6s., and 5 lb. boxes at £1 8s., carriage paid. The photographer whom I asked to test the Photographine sent as sample, says that it will clear a negative very much like many other agents, but that he fails to see its superiority or any advantage in its use.

### 39.—The Airedale Camera in Parts.

Messrs. Watkinson & Co., Harrison Street, New Briggate, Leeds, manufacturers of photographic cameras and scientific and laboratory apparatus, have sent for inspection an Airedale Camera in parts with finished brasswork, with a copy of their latest price list. Although mention has just been made of the Airedale Camera in parts it must not be supposed that the camera itself is not supplied complete, and that it must of necessity be purchased. It may also be bought made up and finished, and some idea of its construction may be gathered from the accompanying illustration. The makers explain that the camera "has been designed to meet the requirements of those who want a really well-made practical and useful article at the lowest possible cost. Although very light, weighing only 2¾ lbs., it is very rigid. The bellows, being attached to the front, prevent any cutting of the picture." It is a double extension camera, and is fitted with rack and pinion. It also has a good leather bellows; a leather handle, by which it may be carried; and a reversing and swing back. It is made in half-plate and whole-plate sizes only. The price of the former, with one double slide is £2 17s. 6d., extra slides being supplied at 9s. each. The price of the whole-plate camera is £3 7s. 6d., the cost of extra slides for this size being 14s. For the price it seems to be well made and well finished, and likely to prove a useful article to those who buy and use it. The same camera in parts—a decidedly new departure for amateurs—is just sufficiently advanced in its construction, and in such a state of finish, that any amateur who is fairly well acquainted with the working of a camera could easily complete it. The *woodwork* consists of the body, ready dovetailed; the baseboard, clamped and ploughed



**Watkinson & Co.'s Airedale Camera.**

ready for rack and pinion; bellows frame, reversing frame, ground glass frame, and extension frame, all mitred, keyed, and glued; slide rails front with circular cut ready for lens; double grooving for one slide and two shutters, clamped and rabbeted. The *brasswork* necessary for completing the camera includes rack and pinion, side struts, milled screws, double hinges, ground glass clips, reversing clips, box-board hinges, front bar, hook, turn-buttons, extension rods, and guide strips. In addition to this there are other necessary parts, which are neither woodwork nor brasswork, but which may be described as "sundries." These are the leather bellows, handle and bridges, ground glass, zinc partition with spring, side clips, and hinges; and in addition to these the screws necessary for the completion and putting together of the camera and one slide. The camera in parts is supplied in three different stages, as follows:—(1) The woodwork, as mentioned in detail above, with flat brasswork unfinished, but with all turned work finished, at 35s. (2) With all the brasswork highly finished and lacquered, 40s. (3) With brasswork finished and lacquered, and one double slide finished completely and ready for use, but not polished, 45s. If a polished slide is desired, an extra charge of 9d. is made. The Airedale Camera in this form seems likely to meet the wants of many amateurs who would like to be able to say that they had made their own camera, but who are not possessed of sufficient skill in joinery and cabinet-making to do all the clamping, ploughing, grooving, and rabbeting that is required in the woodwork. To carry out these operations, the amateur woodworker must not only have acquired considerable proficiency in his adopted art, but must have by him many special tools which amateurs do not usually have in stock. It is a difficult matter beyond doubt to prepare all the parts, but to put the parts together is comparatively easy.

The Editor.

## SHOP:

### CORNER FOR THOSE WHO WANT TO TALK IT.

*In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—LETTERS FROM CORRESPONDENTS.

**Carriage Varnishing.**—H. B. (*Brighton*) writes: 'In bis well-written and practical instructions BAROUCHE on the above subject (see page 123, . 112, Vol. III.), and at the sixth line from the ttom of column indicated, J. C. K., in writing the taking off of hind seat of Stanhope phæton, vises that if the screws, by which it is fixed to dy, cannot be drawn by turn-screw (*i.e.*, screwiver), and are set fast by rust, the heads of ch screws need to be chipped off, etc. Permit to point out that this method should only be sorted to as the very last in a severe extremity. ason—because it is twenty chances to one that so doing the seat end is almost sure to be either lit or severely damaged, sometimes even requirg the ends or bars to be entirely renewed. Havg had all kinds of 'jobbing,' and many years' actice in all the endless ramifications of that anch, I have had to wrestle with hundreds of such rews, and have very seldom failed in withdrawg them, and rarely with any damage to the parts fected. I proceed as follows: Finding by the rn-screw that the screws will not move, in the se of the seat named, I should procure a piece of und iron rod of such a size that, when placed end , the rod is a trifle smaller than the head of rew. The rod may be 18 in. long, or sufficient to ve good 'cold' hand hold at one end when the ber end has been heated. Then have one end ated to a very bright red, and hold it, end on, to ad of fast screw, and in a minute or two that rew can be easily withdrawn with the turnrew. For a number of such I should have two ds to save time—one getting hot while using the her. The wood immediately round the screw ay get just a little singed, but that is of no consc ience, as compared with a split seat end; besides, e saving of time is also a most important item. nd while writing of hot irons, I may mention that here screws become rusted in the plates, etc., of nder carriage work, they can be loosened same ay by holding hot tire bars over three or four at beat, and again save much valuable time. By ese means I have drawn screws which nothing se could be made to move, and I have neither oken a blood-vessel, raised a blister, or turned hair. Another most useful application of the hot on can be effected where, through accident or relessness, bruises may have been made in new, nd even in some places in old, bodies. Thus, ppose a new panel on one of the sharp corner ouldings has received a blow, causing a very ungbtly indentation, proceed in this wise: If bare ood, well soak the part affected with clean cold ater for an hour or two, according to extent of amage; then get a piece of tire bar wider than e bruise, heat to a dull red, and hold near enough as not to scorch the wood, and as the iron gets oler approach it nearer. When cool enough not burn, lay it right on the bruise, and it will, if roperly and carefully done, draw the bruised place ut level with its surroundings, when, if glassapered off, it will never show; but if left in its amaged state and 'stopped' up in the painting, e 'stopper' is always liable to fall out and spoil e whole job. I trust J. C. K. will not feel offended my intrusion upon his ground. Should you, Mr. ditor, think it likely, please do not print this in ours,' if indeed you consider it worth inserting at ll. I am an old Polytechnic student, and had the ood fortune to sit for four or more sessions under at prince of technical teachers, Mr. John Robertn, and I feel an old boy's interest in all these atters; and having a great desire to see coachuilding in all branches more fully developed in ORK, shall always do all I can to further it."

**Rate of Circular Saws.**—ERRATUM.—A. R. *Scorrier*) writes that the letter headed "A Woodorker" (see page 187, Vol. III.) emanates from him, nd is in reply to A Woodworker's letter on page , Vol. III.

**Petroleum Engines.**—C. J. C. (*No Address*) rites:—"If J. H. D., in WORK of May 2nd, 1891, efers to the 'Priestman' petroleum engine, in he second part of his explanation of oil-engines, I ust respectfully correct him on one point, viz., hat the impulses occur at such comparatively long ntervals that they require much heavier fly-wheels, proportion to their power, than steam-engines. o doubt the oil-engines require heavy fly-wheels, nd so do gas-engines, but the 'Priestman' oilngine gets an impulse, certain, every fourth stroke f the piston, or every alternate revolution of the y-wheel. On account of its steady running, it is dmitted to be one of the very best motors for electric lighting, which would hardly be the case if the impulses occurred at long intervals. J. H. D. appears to be correct in his explanation of the mixing of air, vaporising, etc., but the bichromate battery is not of such magnitude as he implies. If I am mistaken, and J. H. D. did not refer to the 'Priestman,' I should esteem it a favour if he would inform me, through this paper, what oil-engine he referred to, as I am not aware of any other reliable except the 'Priestman.'"

### II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**Saw Hammering.**—NEW ZEALAND asks for some plain directions as to saw hammering. The following information will be practical and theoretical. I give two or three very rough sketches, so that NEW ZEALAND may clearly understand me. Fig. 1 represents a saw-plate tight at the centre; when placing the straight-edge on the plate it shows it to be convex, and if you try to push the centre down it will spring back again; to get the plate flat or true, the tight place should be struck on both sides of the plate with the dog-head hammer. Fig. 2 represents a saw tight at and near the rim but loose at the centre; in this case the hammering should be done near the rim, or where it is tight, and with the dog-head hammer. It will be seen that this plate shows itself concave; if the plate is reversed

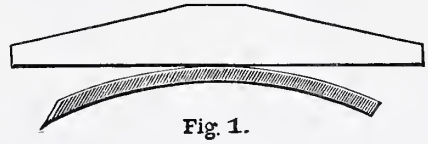


Fig. 1.

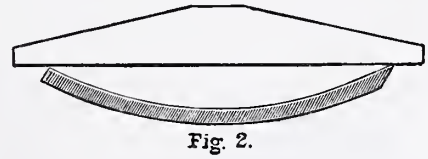

Fig. 2.

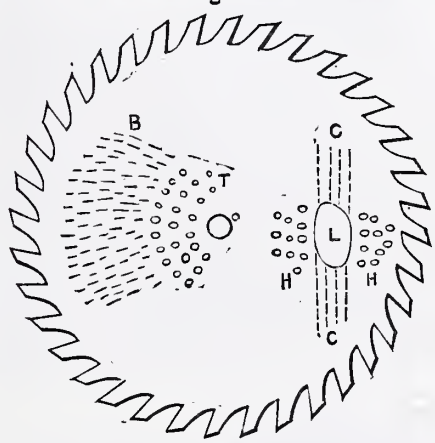

Fig. 3

Saw-Hammering Marks and Bends.

and the straight-edge placed on it, the centre drops with the least touch precisely the same as before, showing that the centre is loose. Fig. 3 represents a circular saw loose or slack at L. To take this out, the plate should be struck with the cross-faced hammer, as at C C, and with the dog-head, as at H H, or it may be struck all round with the dog-head hammer. By your statement of your 12 in. saw it must have been stretched on the outside, or rather at the rim, and pinched or twisted. I have often seen saws in this condition, but have never got them perfectly true, but if put into the hands of a man who has learned the whole art of hammering they may be made perfectly true. The way I proceed with a saw in like condition is to hammer all round the plate on both sides with the dog-head hammer, as at T, in Fig. 3, then with the cross-faced hammer all round the plate, as at B, and I have in most cases got the plate true enough to do good work.—A. R.

**Bicycle Wheels.**—H. R. (*Ewell*).—Get a shilling bottle of cement for mending cuts and splicing tyres at any cycle warehouse. Make the spliced surfaces very clean, or cut them anew with a sharp knife dipped in water. Get a bottle of Snell & Brown's Octopus cement. Smear both the splicing surfaces, and let stand for two or three hours before sticking together; then place the splices evenly and press together, and it will at once be ready for use on the wheel. With Lucas's cement you smear the splices and stick together at once, but the tire should stand for an hour or two before putting it on the wheel or using.—A. S. P.

**Bicycle Plating.**—F. S. (*Bristol*).—There is no stuff that can be put on to serve for plating. Send the parts to be plated to a regular nickel-plater's. You do not require to do anything with them in the way of preparation, except perhaps removing paint. They will prepare the articles for the bath themselves.—A. S. P.

**Painting on Silk, etc.**—SILK BANNER.—Before painting or gilding, so much of the space as is to be covered, *and slightly beyond its outline*, must be sized. This is to stop absorption, and to prevent the oil from running. A preparation for the purpose is sold at artists' colour shops, or may be made by dissolving isinglass in water or by boiling down cuttings of parchment. For gilding or silvering, oil gold size can be used on this ground; and for painting, ordinary tube oil colours. To prevent cracking, care must be taken not to lay on the colour too thickly, but to thin it down well with turps. It is better to attain the desired depth of colour by two thin coats than by one thick one. As regards varnish: if the colours are found to dry equally dead throughout, varnishing becomes simply a question of taste. Some prefer the dead painting, which shows equally in all lights. But should the colours dry dead in some parts and bright in others, varnishing becomes necessary to glaze them all alike. Some mix a little varnish with their colours, and thus get a sufficient glaze throughout.—S. W.

**Incubator.**—H. H. LINDON (*Higher Bebington*).—You are, unfortunately, not the only one who has found the same difficulty with the machine described in No. 89, Vol. II. You certainly will not get 104° in the egg drawer with the tank heat only 116°. The remedy therefore is: use more heat—a larger burner—although I must say a burner taking a 2½ in. wick ought, in my opinion, to be sufficient. Roughly speaking, tank heat should be almost double that required in the egg drawer. Turning to the article in question, I find a case measuring 16 in. by 16 in. outside is recommended, made of ¾ in. stuff, and a boiler 15 in. by 15 in. How the latter can be fitted into the case, besides leaving room for packing, is a poser. In my own experience with a 16-egg hot-water machine, I found 2 in. of sawdust packing round and above boiler, and round egg drawer also, to be about right, and could, with a burner taking a ¾ in. flat wick, get 120° in egg drawer. Judging from this, it seems to me that your machine needs padding to keep the heat in, in which case it would hold only about sixteen to twenty eggs, instead of thirty. This meaning a lot of trouble, I would advise you to put your machine away for the present, and await the appearance of my article on a Hot Air Incubator, to which you may be able to adapt your present case without much alteration, and which, I am sure, will give you satisfaction.—LEGHORN.

**Incubator.**—INCUBATOR.—Why a zinc tank should become eaten through and leak after twelve days' use is a mystery I should like solved. What zinc did you use—new or old? What did you use as a flux for soldering? and did you take care to wash off all the surplus fluid? If killed or unkilled spirits (so called) were used, and the joints left unwashed after soldering, it would account for a little, or perhaps all, of the trouble. If you took this precaution, the only solution of the matter lies in the fact that some powerful corrosive must have, by some means, been introduced into the tank. Pure rain water certainly cannot be answerable for it, so I can only conclude that it became contaminated before use. For the future, use ordinary fresh water. The small amount of lime it contains will make no difference. Your second experience is equally strange, and I can offer no explanation why a tinned iron tank should absorb more heat than a zinc one, unless your iron is very much stouter than the zinc. The only remedy I can suggest is to reduce size of tank, and use more packing.—LEGHORN.

**Bird-Cages.**—BYKER.—The articles on the above appeared in No. 54. Other small hints on the construction are given in "Shop."

**¼ H.-P. Engine.**—G. P. (*Camberwell*).—Articles are not run on in consecutive numbers of WORK, but every series of articles is completed in the volume.

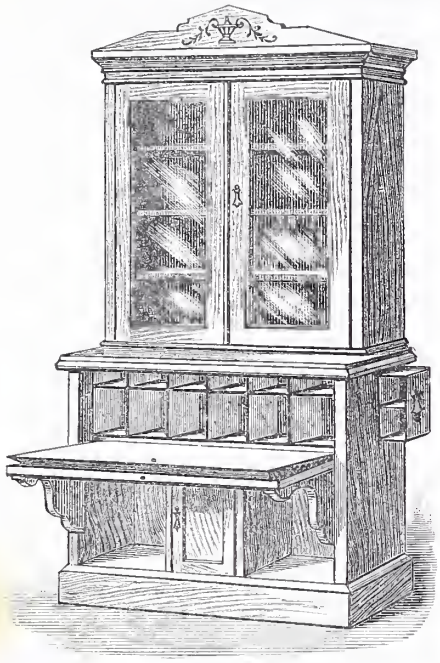
**Fretwork Machine.**—J. J. (*Fenton*).—Consult the Indexes of WORK, Vols. I. and II. Much has already appeared upon Fretwork Machines.

**Making Lantern Condensers and Objectives.**—E. R. N. (*Forest Gate*) and others.—Read reply to F. J. D. (*Stoke Newington*), on page 219, and write again should any difficulty arise.—C. A. P.

**Brooklet.**—ADMIRER OF "WORK."—If you can get some strong blue clay, and make it into a puddle, and lay the bed of the stream 6 in. thick, I do not think many worms will get through. The puddled clay must be carefully laid, especially at the joins, which should be cut on each side with a 4 in. tool, the cuts filled with water, and well kneaded with a pair of heavy boots till in one mass. As an additional precaution, before laying on the puddled clay, cover the surface with slaked lime or soot. The clay should be pure and tough, and free from any admixture of stones, loam, or gravel. You will require about thirty-five cubic yards of clay if it is required the full length. If you cannot procure clay of this nature, lay a foundation of broken stones, 3 in. or 4 in. thick, and cover this with cement concrete 2½ in. thick, formed of five parts of crushed bricks or limestone and one part of Portland cement. Lay it in lengths of 6 ft., having boards laid to the proper shape at each end. In laying miss every alternate length, and when these are set fill in the spaces left, levelling them to the

work already done. When the concrete is laid in this manner, it is not so liable to crack as if laid straight on. The foundation should be well beaten down before laying on the concrete.—M.

**Bookcase and Writing-Desk.**—AMBIGITUR.—There are several varieties of bookcase, the lower portions of which can be immediately transformed into writing-desk, exposing pigeon-holes. The article I have designed follows the usual run of such things, with the exception that I have introduced one or two new, and I think serviceable, features. It is advisable to make it in two carcases screwed together. Of the top carcase, nothing further need be said than that sufficient instructions applicable thereto have appeared in past numbers. In the lower carcase there is a small bottom cupboard and a set of pigeon-holes enclosed by a flap-door, the latter being used as a writing-desk. To facilitate its use as such, it is intended that a bracket be hinged to the inside surface of each sideboard. Bookcases are generally made 18 in. deep from the wall. It will be seen, therefore, that if the front of the pigeon-holes are flush with the front of the job, difficulty would be

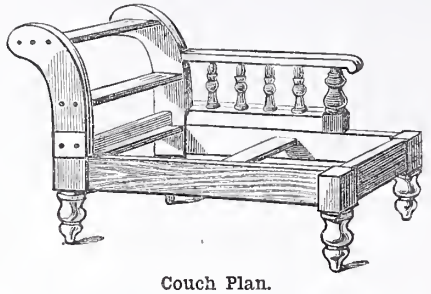


Bookcase and Writing-Desk.

experienced in obtaining any papers which happened to be far back in them. To avoid this, the front of pigeon-holes is usually some distance back, the result frequently being that the space in front of them is comparatively useless. By adopting my suggestion, all space will be utilised. Fit pigeon-holes as shown, and in back part of each sideboard cut hole to admit a set of compartments to move inwards and outwards drawer-wise, running on board to which front flap is hinged. It would be a handy course to take, also, to have a thin leather-covered board hinged at the back to the top surface of the writing-flap, with the ends closed in with loose material to form a receptacle for odd papers. For suitable details of construction, read Mr. Adamson's "Some Lessons from an Old Bureau," and other articles. Height of bottom carcase from floor, 3 ft. 8 in.; width of writing-flap, 12 in.; width of job, 3 ft. 6 in. Study dimensions a little, however. —J. S.

**Batteries for Working Electro-Motors.**—R. C. (*Mayfield*).—The cells of a battery to work an electro-motor should be large, because a large volume of current is needed to drive the machine, and this can only be safely taken from cells having a large capacity for furnishing a volume of current. Each cell should hold not less than one quart of liquid when the plates are immersed, but will be more efficient if made to hold half a gallon of liquid. The plates should be as large as the capacity of the cell, because large plates offer less resistance than small plates. In single fluid chromic acid or bichromate cells, two plates of carbon should have one plate of zinc between them in each cell. Large salt jars, pickle jars, or pickle bottles make very good single fluid cells. The charge for these is made up of 1 lb. of chromic acid and 2 ozs. of chlorate of potash dissolved in one quart of water, to which must be added, drop by drop, 7 fluid ozs. of sulphuric acid. The zinc must be well amalgamated, and should be thick. A good arrangement for the plates is shown on page 36, Vol. III., of WORK. The double fluid chromic acid battery, with dilute sulphuric acid to excite the zinc, and also the Bunsen battery, of similar construction, are both suitable for working electro-motors. See also reply to Mac, p. 93, Vol. III., of WORK.—G. E. B.

**Couch.**—J. N. (*Cork*).—A couch or lounge constructed like sketch would simply require framing together like a table frame. The legs should be turned out of 4 in. hard wood, and two of them kept about 4 in. longer than the others on the square; and the scrolls, which are made of 1¼ in. hard wood, are halved and screwed on to the squares. The rails across the scrolls are grooved in about ½ in. deep, and nailed from the outside. The back can be made first, and a stump at the end is framed into the seat rail, into which two flat rails are fitted to receive the turned spindles: the bottom one to be tenoned into the stump at one end and halved on to the scroll at the other end and screwed; the top one to go



Couch Plan.

on to the stump with a good 1 in. pin and halved into the scroll at the other end; this one receives the stuffing, and should be about 2½ in. wide. It will be seen in sketch that a middle rail or stretcher is put in to give strength; if the couch is short it will not be needed. Sizes: 4 ft. 6 in. long on frame, 20 in. wide; from bottom of leg to top of seat rail, 14 in.; height from floor to top of scroll, 2 ft. 8 in.; height of back from floor, 2 ft. 3 in. This is the size of a very short couch; you must use your own discretion about length, etc., as sizes vary to suit circumstances.—H. H.

**Case for American Clock.**—J. W. (*Kendal*).—I will leave you to decide upon the dimensions, thicknesses, etc. You cannot go far wrong in so small an article. As you are going to use a battery in addition to the small American clock, I advise you to place the former within the case, underneath the clock, if such a position is not unsuitable. Have a solid board, with a piece half circular in shape cut from it at the top, screwed within the case at the back to assist in supporting the clock. In the front of the case fix a similar piece, but let it be merely a frame, as in Fig. 2, to permit of the introduction of the battery, etc. You could, however, hang the clock within the interior by means of the ring above it. Fig. 2 explains the construction. It is an upright section. Two sides will be joined to a moulded top board, the bottom edges of them being rebated over stout plinth boards, the latter being mitred and screwed. A bottom board will be joined into the plinth pieces as shown. The back board should fit into rebates on those parts which it comes in contact with. The door can fit within the sides, or merely be hinged over their edges, as shown in Fig. 1; and it is an optional

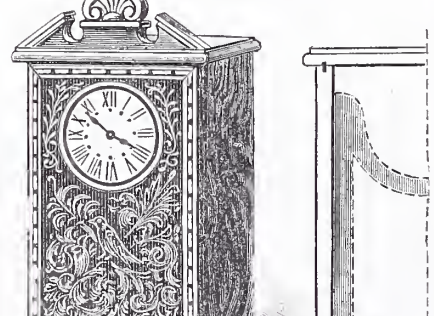


Fig. 1. Fig. 2.

American Clock. Fig. 1.—The Case. Fig. 2.—Section of Case.

matter whether it is mitred or mortised and tenoned together. Rebate it to receive the glass, which should be left clear in the upper half to expose the clock face, and painted upon the lower portion. (See indexes for articles on glass painting, recently published in WORK.) The pediment will be merely glued and screwed to the carcase. Small brackets at the sides will be found useful and ornamental. In Vol. I. there appeared a design and copious details of a very pretty clock case in wood: see it for yourself if you do not already possess it. —J. S.

**Aphengescope.**—WELL-WISHER.—The aphengescope, megascope, or opaque lantern, as it is sometimes called, is a very interesting optical instrument used for the purpose of projecting enlarged images of opaque objects upon a lantern screen. The aphengescope, as illustrated in Figs. 1 and 4, is a sort of angular box made to fit on to the draw tube of the slide stage of an ordinary optical lantern in place of the objective, which is removed and screwed into a flange attached to the front of the instrument, the object to be illuminated being placed in the body of the aphengescope facing the aperture by which the instrument is attached to the lantern. On the lantern being lighted, all the light emitted by the jet is concentrated full on the object by the condenser, and the achromatic lens in turn collects these rays and projects the image upon the screen in the usual manner, the lanterns, on account of the formation of the instrument, being placed with their backs towards the screen. The sole requirement of an aphengescope may be said to be: plenty of illumination, no matter from what direction it comes so long as it is sufficiently powerful to brilliantly illuminate the object to be exhibited. As the loss of light by reflection is so great, the instrument will be found to be almost useless for use with an ordinary oil lantern, and even a single limelight jet is barely sufficient to give a disc of a larger diameter than about three or four feet, but by means of the double form of aphengescope shown in Figs. 2 and 3, and

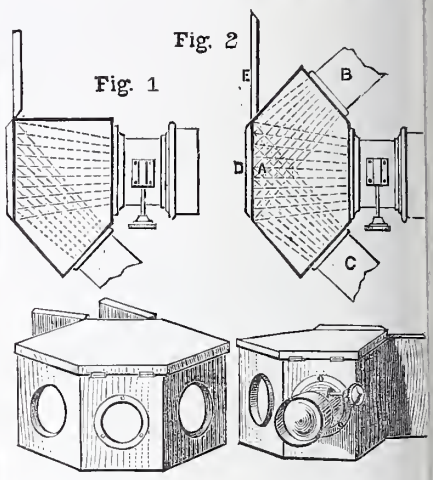

Fig. 3. Fig. 4.

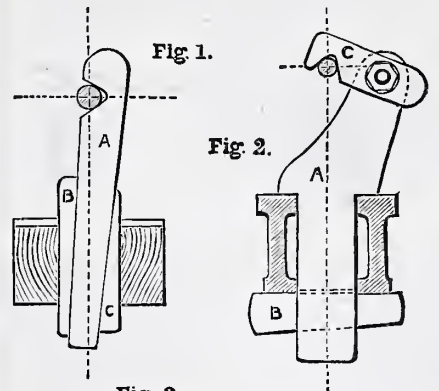
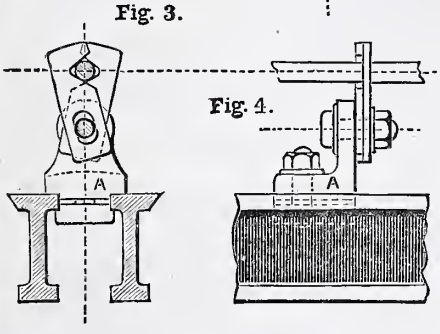
**Aphengescope. Figs. 1 and 2.—Plan of Interior of Single and Double Aphengescope. Fig. 3.—Appearance of Double Aphengescope when complete, showing Doors at Back. Fig. 4.—Appearance of Single Aphengescope, with one Door shut.**

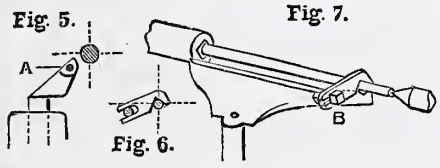
biunial lantern, *which will take apart*, it is possible to show a well-lighted disc of about six or seven feet in diameter. The double aphengescope, which is a slightly different form to the one previously described, is a wood or metal box, hexagonal in shape and provided with circular apertures in three of its sides. A couple of these holes receive the light from two lanterns, the objectives of which have been removed, and the third aperture, which occupies a central position between the other two at the front of the instrument, is provided with a metal flange to receive the objective from one of the lanterns, the objects to be exhibited being placed against the side of the box opposite to the lens. The construction of the double aphengescope is clearly shown in Fig. 2, in which it will be seen that the object placed at A is strongly illuminated by the light from the two lanterns, B and C, which are thus brought close together with their heads toward the screen, and a lantern objective is then screwed on to the front of the instrument in the same manner as it was an ordinary lantern. Two doors, D and E, are so hinged to either side of the back that when one is open the other is shut; it will also be found an advantage to have the top and bottom of each door fitted with a narrow groove on the inside, as this will serve as a means of attachment for cartes-de-visite, allowing one to be slid into the grooves ready to be shown whilst the other is being exhibited. The dimensions of the instrument are immaterial so long as the principle is retained. You can therefore construct one of either form described above of suitable dimensions according to the objects you intend exhibiting; a useful size is one having the six sides about eight inches square. You can employ wood or metal in the construction of this instrument, but I should strongly advise you to make the body of good sound dry mahogany if you are a good hand at woodwork. The sides are nailed and glued to the base, which is formed of a piece of sound wood cut to the plan of Figs. 1 and 2. If formed of wood, you may with advantage fit and hinge a metal lid to open up towards the front, cutting the metal of a sufficient size to allow of a half-inch rim. A couple of narrow rings of brass tubing of sufficient size to just slip on to the draw tubes of the lantern fronts may be fitted into the

tures cut in the woodwork at B and C, and then red to the inner edge of the woodwork by ns of nails or screws driven through holes hed or drilled in the metal. The door should f wood, furnished with grooves at the top and om for the reception of cards as before deed. For the objective, what is required is a of fairly long focus and large diameter, in order it may pass plenty of light. The most suitable for this purpose will be a half-plate photoher's portrait combination. If your lantern, or erns, are fitted with ordinary achromatic comtions, one of these will be found to answer very , but not so well as a half-plate portrait lens, be reason above stated. To arrange the double of instrument ready for use, the objectives are removed from both the lanterns, which are placed with their backs towards the screen. aphengescope is now made to slide on to the tubes of the two lantern fronts by means of couple of brass collars, after which one of the ern objectives should be screwed on to the ge attached to the front of the instrument. If photograph or other object to be shown by the ected light emitted by the jet is placed against back of the instrument immediately behind the ctives, and the lantern is lit up, the light tted by the jets will illuminate the object, which hen projected by the lens in an enlarged form n the screen, and instead of a transparent ure being shown upon the screen, we get a liantly illuminated representation of some solid, perhaps moving, object. When any diagrams, wings, or cartes-de-visite, are being shown, they simply slipped into the grooved rails at the top bottom of the two doors at the back of the rument, and by this means one picture can be wn whilst another is being put in position upon other door ready to take the place of the first. er objects are either held in the hand of the rator, or placed upon the floor of the instrument. objectives will, of course, require focussing in usual manner. The aphengescope will be found y useful to microscopists, who will thus be ened to show upon the screen various opaque ects which it would be impossible to exhibit by inary means. The works of a watch, coins medals, sections of various kinds of fruit, lls, shell fish, moths, butterflies, minerals, and, in rt, anything that cannot be photographed, or ich should be shown in its natural colours, will m a suitable subject for exhibition by means of aphengescope.—C. A. P.

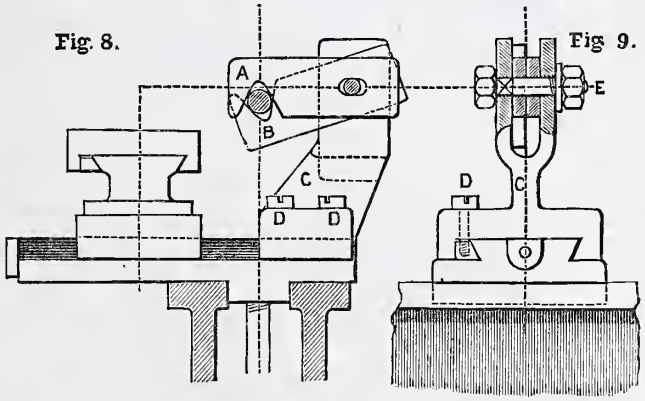
**Backstay.**—R. W. M. (*Co. Kildare*).—To prevent work from chattering when thin and turned ween centres, you require what is called a *kstay:* these are of two kinds, the *fixed* and *travelling*, which latter moves along with the l, whilst the first is fixed to the bed, and is ved along, as you suppose, "as work proceeds." I think the backstay has not been mentioned ore in WORK, and as you will be able very easily it up for yourself this useful attachment, I will cribe one or two kinds of fixed stays. To steady work when turning ramrods, I believe the ner uses nothing but the fingers of his left nd; I have never seen this done, and could not it myself, but I can fancy it would be possible. e next simplest way is to make a notch in a bit of rd like Fig. 1, and fix it in between the shears b wedges. You see it is a very simple matter en all you require is to steady a long piece of od, such as a wicket, etc. The wood smokes and s blackened where it rubs against notch, and shows you the possibility making fire, as the Indians do, by bing two pieces of wood together; would, of course, put some grease to The piece of wood (A) and the wedges y be from ¾ in. to 1 in. thick; the otch can be brought forwards by cking up the wedge (B) and down wedge (C). In Fig. 2 you have a better n which, I think, would suit you well wood. Here A is a piece of hard od, such as oak, about 1 in. thick; is a wedge, passing through a mor-, by means of which A is held firmly n upon the lathe-bed: through the per end of A there passes a bolt, and its means is secured a plate of iron ut ¼ in. thick, having at one end a otch, and at the other a slightly elonged hole for the bolt. The bracket of od (A) being placed on the bed and ured by the wedge (B), the plate (C) is ned over so as to rest its fork upon a ned part of the work to be steadied; n the bolt is fixed, and after applying ttle grease you may go ahead. In Figs. 3 and 4 seen a plan which may be adopted by those who ve a little bracket like A A, which is used to port the boring collar, and supplied with comte lathes; here we dispense with the wooden port, and require only two plates with notches, united thickness of which will about equal that he boring collar. Figs. 5, 6, and 7 show a plan trived (but never carried out) when intending to n a number of ¼ in. spindles of rosewood about long; it was, however, found quite possible to witbout any support; yet the plan looks prosing for very small work, and it is herewith sented to the readers of WORK. A new T is uired for the rest, seen sideways at Fig. 5; s only differs from the usual form in having the per edge thicker, so that a $\frac{3}{16}$ in. hole (A), shown ck, can be drilled and tapped into both ends; then two little pieces of steel would be made like Fig. 6, about 1½ in. long, and a $\frac{3}{16}$ in. screw (B, Fig. 7) provided to fix them. The view at Fig. 7 will suffice, instead of further description; the first 2 or 3 inches of the work are turned without any steadying appliance; then the screw (B) is put into the end of the rest, the little plates with their V-notches slipped into it, clasped by the fingers into the turned part, the screw fixed, and all is ready to turn 2 or 3 inches more. Thus far we have dealt with fixed backstays, which are secured to the bed; but you have a slide-rest, and would probably like to know how to fit one into the slide-rest itself, so that it may hold the work close up to the tool. This will be still a *fixed* stay, as it does not follow with the tool, keeping the same distance from it, but is fixed to the lower slide of a slide-rest, and not upon a moving saddle as on a slide lathe. Figs. 8 and 9 show a side and back view of a slide-rest backstay that has just been made to my design by Mr. Chas. Taylor, of Bartholomew Street, Birmingham; it fits one of his 3½ in. slide rests, and I have put into Fig. 8 a few lines to represent a slide-rest, just to show how the backstay fits on. Here we have the same two notched plates (A and B), but as we are now dealing with metal turning they will require holding very firmly: C C is a casting which slips into the cross-slide of the rest, and is secured by pinching the screws D, D; A B are then adjusted, the nut E firmly fixed, clamping the forked sides of the bracket C upon the plates A and B. The appliance is very quickly put in position, and as quickly removed. The plates A, B, are of iron, case-hardened. The travelling backstay is usually made to fix upon the saddle, as this one does on the fixed slide-rest; it is generally made to take two wooden dies, by means of which the work is steadied; of course, wood does not mark or scratch the work, but then the wood dies must be made and adjusted.—F. A. M.







**Backstay. Fig. 1.—Simple Backstay. Fig. 2.—Better Form. Figs. 3, 4.—Stay for Slender Turning fixed to Boring Collar Support. Figs. 5, 6, 7.—Proposed Form of Stay for Slender Turning. Fig. 8.—Side View. Fig. 9.—Back View.**



**Paper Staining.** — DOWN. — Paper-stainers' colours are prepared much after the way of decorators' distemper. The firms purchase their colours in dry powder form—blue, red, yellow, etc., of varying degrees of purity and brightness. Whiting of a fine quality forms the body for the bulk of paperhangings, excepting, of course, sanitaries and so-called washable papers. Read the chapter on Distemper in "Plain and Decorative House Painting," Vol. I.—F. P.

**Varnish.**—J. B. (*Durham*).—Varnish prepared from shellac and methylated spirit, or of similar nature, such as French polishers use, is about the only variety that can be successfully made by the individual worker. If your query refers to painters' copal-oil varnish, you may at once dismiss the notion of making it from your mind.—F. P.

**Painting Bird Cage.**—BIRD FANCIER.—The reason of the enamel paints you have used on the inside of bird cages not drying is probably due to greasiness of the cage, or the enamel may be stale, or else you have put too much on, and it is only surface-dry, and not hard throughout. I would advise—assuming they are wire and metal cages—that you give a first coating of flatting paint made with white lead, or zinc white, and diluted to working consistency with two parts turps to one of Japan gold size. This will form a good ground or "key" for enamel, and if it does not then harden, the enamel is at fault. Ordinary patent size is the cheapest thing to prepare wood for staining with. It raises the grain of the wood slightly, but answers well for all common staining, and prevents the sappy parts becoming darker than the remainder. If best effects are wanted, varnish or Japan gold size may be used instead of size before oil staining.—F. P.

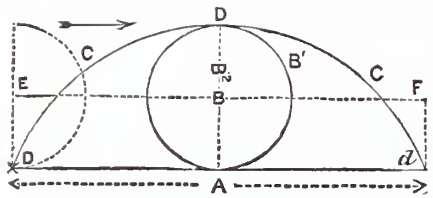
**Colouring Kitchen.**—D. P. V. (*London, S.E.*).—Ordinary wall colouring or distemper is prepared from size and whiting; the addition of dry powdered pigments gives the tints. For yellow, or rather buff, wall colour, soak 14 lbs. of whiting in sufficient water to slacken it, putting the whiting into the water. Pour off superfluous fluid, and add the colouring powder—Venetian red for pinks, lime blue for grey or light blue, and ochre for buff. These used separately, or in mixtures, will give a great variety of tints for common purposes. Having well mixed in the colouring, try a little by drying on paper, and when the desired tint is obtained, add to the above four pounds of warm patent size, or about one pound of glue properly dissolved. Before following these directions, obtain the new circular, etc., of Alahastine, from the Church Manufacturing Company, 127, Pomeroy Street, S.E.—F. P.

**Bicycle Wheel.**—PARALLAX.—(1) The wheel is out of truth, and requires to be trued up. If the spokes are direct, procure a spoke grip, costing about 1s. 6d.; if laced or tangent, procure a nipple key, costing 1s. Revolve the wheel, holding a piece of chalk at the side of the rim. The rim will touch the chalk at the parts out of truth. Tighten all the spokes on the *opposite* side of the chalk marks if they are loose. If they are tight, slacken all the spokes *on* the side of the chalk marks. Wipe off the chalk with a rag, and revolve wheel again, letting the untrue parts touch the chalk as before. Continue slackening spokes at the marks on the chalk side, and tightening on the opposite side. If you are not equal to performing this bit of work, send the machine out to a qualified repairer. (2) Cement for fastening tires can be bought at the cycle shop for 9d. to 1s. per pound, or in 6d. boxes, so that it is not worth anybody's while making it, even though he knew how.—A. S. P.

**Picture Cords.**—T. W. M. (*Burslem*). — The plan sent us, so far as we can see, is novel and useful, as well as ingenious, and certainly worth patenting, as it would answer its purpose well, besides being simple and ornamental. We think our correspondent would not be acting wisely if he did not turn it to some account, there being nothing to gain by giving it away, and letting others reap the benefit of that which he is clearly entitled to, as the product of his own inventive ingenuity. We should strongly advise him to make a search at the Patent Office Library to ascertain all that has been done in this direction, so as to see his road clear, and, if so, to go ahead with his patent.—C. E.

**Speed of a Wheel.**—C. C. (*New Cross, S.E.*).—The great difficulty in making ordinary people understand the fact that the upper part of a wheel of a cart, cab, omnibus, carriage, or locomotive, is travelling faster than the lower part, when either is in motion, arises from their being unable to dissociate their ideas from the case of a wheel fixed on a shaft or axle, which shaft or axle revolves in a fixed or stationary bearing, like the

fly-wheel of a steam, gas, or other engine used in driving machinery. In this case the wheel revolves with equal velocity over all its circumference, but the moment this wheel and its axle and bearing are caused to travel along a surface, another set of conditions come into play which did not exist in the former case, and then a compound movement takes place. First the wheel or shaft, or axle and bearing, travel along a surface, and whilst the axle and bearing travel in a line parallel to that surface over a distance equal to the circumference of the wheel, a point in the revolving wheel is describing, by the motion of its circumference, a curved line which is longer than the path travelled by the axle and bearing. Therefore, it must follow that to travel the same distance in the same time, a spot on the wheel must have travelled faster than the axle and bearing, to have described the curve which is a longer distance than the axle and bearing travel, and come again to the similar spot over the surface from which it started, in the same time. In order that this may be easily seen, we have appended the following diagram, a little study of which will make this clear and apparent to anyone. In this diagram the cycloidal path of a given point on the circumference of the wheel, starting from the surface on which it rests until it comes again over a point on the surface from which it started, may be readily seen, and if a model wheel be made of, say, 6 in. in diameter, and a piece of wood or hoard of, say, 2 ft. long be used as the surface on and along which it is rolled, it will be seen and proved that a complete revolution of the wheel will bring the point on the wheel, which was over the surface at starting, over another point of the surface at a distance equal to the circumference of the wheel from the point where it was when it started, hut that to get there it must have travelled along the curved line, which is always longer than a straight line hetween two given points, at a faster rate to do a longer distance in the same time. In the diagram, the line A represents the

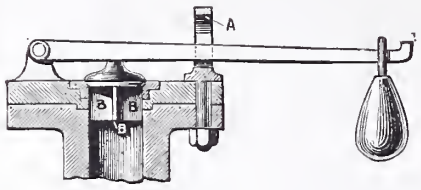


Cycloidal Curve.

distance over which the wheel has to travel, the axle moving from E to F on the dotted line. The dotted wheel shows the position of the spot D on its circumference at starting; C C shows the curved path of the spots travelled by it until it comes to a similar position on the surface at *d*, having travelled from left to right, as shown by the arrow; B shows the position of the axle, and B′ that of the wheel, when they have completed one-half of their journey, the spot D being now at the top of the wheel, having ascended the rising half of the curve. As it goes on, it describes the falling curve to *d*, where it again resumes the same position in regard to the surface as it had at starting, and so long as the wheel travels, so this spot will always continue to perform the same thing. Anyone who has watched the wheel of a hansom cab when at speed, can hardly have failed to notice how the centrifugal force throws the mud and dirt from the top, and not the bottom, of the wheel, which could not be the case if the lower part travelled with equal velocity. The formula for the diagram is as follows:—Length of the base line A=3·14159 $B^2$; $B^2$ the generating circle = ·31831 A; length of curve C C=4·$B^2$.—C. E.

**Polish Reviver.**—A. E. S. (*London*).—I am always chary about recommending to inexperienced hands any reviver containing methylated spirits or naphtha. I can well recall to mind ten years ago selling a bottle of reviver, the chief ingredient of which was spirits; my customer had a valuable piano, on which she first tried her 'prentice hand, thinking that the more liberally she used the reviver the better the results would be. Alas! this mistaken idea nearly spoiled, instead of improved, the polish. This incident, though it found me a day's work to rectify the damage, etc., serves to show that, though experienced hands can use such revivers with advantage, it is well to warn the inexperienced to use anything containing spirits with caution, and I strongly recommend using the spirits in the finishing rather than the cleaning stage, as in the following recipe, which I have used almost daily for the last four years—so giving a fair trial, and for the purpose you name; viz., "keeping your recently polished bookcase in a bright and fresh condition"—and which will, I trust, do all you might desire. Reviver: ½ pint lime-water, ¼ pint linseed oil, ¼ pint sweet oil, ¼ pint turpentine. Mix the lime-water and linseed oil by well shaking, then add the sweet oil; when thoroughly incorporated, thin down with turps. Shake up when using, and apply, rather liberally, with wadding or soft rag, rubbing all over; wipe off with a soft rag, fairly damp with methylated spirits, changing the face of the rag occasionally to enable you the better to remove all greasiness and smears. You may then, if you like, touch up any carvings or mouldings with a little French polish or spirit varnish, applied with a camel-hair brush.—LIFEBOAT.

**Valve.**—E. F. (*St. James's*).—In any well-designed safety-valve, the valve should not be able to be removed from its seat without, as you remark, first removing the pin in the end of the lever. In order to prevent the valve being blown out of its seat, there is generally a guide for the lever which allows it to lift sufficiently for the proper escape of the steam through the valve, and is then stopped by the top of the slotted guide A, which can be seen in the accompanying sketch of an ordinary safety-valve. The valve itself should be provided with



Valve.

three or four wings (B), which guide it vertically and prevent it being blown sideways by the escaping steam. This is the commonest form of safety-valve; and some are made without the guide (A), but very few indeed, in which case, by swinging the lever over, the valve can be removed without taking out the pin. The various spring safety-valves, which are innumerable, almost always have some contrivance to prevent the blowing out of the valve.—P. B. H.

**Walking-Sticks.**—E. H. (*Sunderland*).—The following are addresses of makers and carvers of walking-sticks: Henry Howell & Co., 180, Old Street, London, E.C.; J. Slugg, 27, St. John's Road, Hoxton, London, N.—H. W.

**Model Electric Lights.**—T. T. (*Harlesden, N.W.*).—Consult the Indexes to Vols. I. and II. of WORK.

**Camera.**—G. M. F. (*Falmouth*) will find in WORK, Vol. I., full particulars for constructing a whole-plate camera from one of the best makers' designs—that of George Hare. Every maker in the present day introduces some variation in pattern or movements—many of which are unnecessary, and only add to the complications of the instrument, which cannot be too simple, provided the really useful movements are retained. With regard to the quarter-plate size, if the principal measurements given are reduced to a fourth, you will practically have all the information you require. Of course, in such a small camera the woodwork may be made lighter, and some of the clamping neglected. The length of the bellows is quite arbitrary, so long as the length is sufficient for the lens used. It is quite impracticable to supply you with working drawings for any camera. If Underwood's is the one you have decided on, we see no other way out of the difficulty than that you should procure one and copy it. As to the lens, so much depends on the kind of work you intend doing. The best plan is to be provided with several of different focal lengths. If you are limited to one, there is nothing better than Dallmeyer's rapid rectilinear lens, of 6 in. focus; and the next most useful is a Ross symmetrical, of 3 in. focus. There are now so many good lenses in the market that we cannot particularise them; those mentioned are universally approved standard instruments, and if they are used properly, any shortcomings in the photograph cannot be attributed to their inefficiency. For *interiors* a wide angle rectilinear is almost necessary, other kinds not including enough subject, especially in confined spaces.—D.

**Xylonite.**—G. A. B. (*Normanton*).—Write to the manufacturers for their prices.

### III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Wood-Turner's Pattern Book.**—T. F. (*Aberdeen*) writes:—"I shall feel obliged if any reader will tell me where I could get this."

**Crystoleum Painting.**—PAINT-BRUSH writes:—"I find that when a photo is fixed on the glass with corn-flour paste, that three out of four times it shrinks away and puckers at the edges. Would any of your correspondents tell me another medium I can use to do the same?"

**Buff Leather.**—R. S. (*Gloucester*) writes:—"Will any reader kindly inform me where I can get buff leather such as soldiers' belts are made of, with price per pound?"

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—EDISON PHONOGRAPH CO.; HOPEFUL; F. J. (*Rochdale*); W. R. R. (*Carlisle*); A. F. (*Dublin*); YOUNG ENGINE DRIVER; N. D. P. (*Manningham*); M. G. H. (*Smethwick*); J. T. (*Rawtenstall*); G. A. H. (*Islington, N.*); LITHO; A. R. (*Scorrier*); B. C. E. (*Birmingham*); E. L. C. (*Portland*); J. B. W. (*Salford*); W. G. C. (*Sierra Leone*); G. P. (*Gloucester*); INVENTOR; J. W. H. (*Chesterfield*); J. E. P. (*Accrington*); GOOD IRON; POLISHER; W. C. R. (*Glasgow*); J. G. (*Edinburgh*); W. J. (*No Address*); W. J. (*Portsea*); AMATEUR MECHANIC; J. D. (*Hull*); C. F. (*Sherborne*); BOOKWORM; L. S. (*Beaverstown*); SELF-HELPER; W. T. (*Stratford-on-Avon*); F. P. (*Dover*); T. S. (*Manchester*); W. B. & SONS (*Edinburgh*); J. P. A. (*Walthamstow*); G. M. (*London, E.C.*); H. B. (*East Hartlepool*); E. W. (*Chingford*); M. G. B. (*Poplar*); AN OLD EDISONIAN; A PLAYER; LEMUR; F. W. R. (*South Shields*); HOUSE PAINTER; S. A. (*Burnley*); R. C. (*Mayfield*); J. H. (*Cork*); NERO; A CONSTANT READER; T. R. (*Ashton-le-Willows*).

## MANUALS OF TECHNOLOGY.

**Edited by Prof. AYRTON, F.R.S., and RICHARD WORMELL, D.Sc., M.A.**

**The Dyeing of Textile Fabrics.** By J. J. HUMMEL, F.C.S., Professor and Director of the Dyeing Department of the Yorkshire College, Leeds. With Numerous Diagrams. Seventh Thousand. 5s.

**Steel and Iron.** By WILLIAM HENRY GREENWOOD, F.C.S., M.I.M.E., etc. With 97 Diagrams from Original Working Drawings. Fifth Edition. 5s.

**Spinning Woollen and Worsted.** By W. S. BRIGHT MCLAREN, M.P., Worsted Spinner. With 63 Diagrams. Second Edition. 4s. 6d.

**Cutting Tools.** By Prof. H. R. SMITH, Professor of Mechanical Engineering, Sir Joseph Mason's College, Birmingham. With 14 Folding Plates and 51 Woodcuts. Third Edition. 3s. 6d.

**Practical Mechanics.** By J. PERRY, M.E., Professor of Mechanical Engineering, City and Guilds of London Technical College, Finsbury. With Numerous Illustrations. Third Edition. 3s. 6d.

**Design in Textile Fabrics.** By T. R. ASHENHURST, Head Master, Textile Department, Bradford Technical College. With 10 Coloured Plates and 106 Diagrams. Third Edition. 4s. 6d.

**Watch and Clock Making.** By D. GLASGOW, Vice-President, British Horological Institute. Second Edition. 4s. 6d.

## *SALE AND EXCHANGE.*

**Victor** Cycle Co., Grimsby, sell Mail Cart Wheels. [7

**Who's Lunt?**—Why, the Best Man for Joiners' Tools of warranted quality. Send stamp for our Seventh Edition Reduced Price List.—LUNT, Tool Merchant, 297, Hackney Road, London, E. [9

**The Universal Amateur Exchange.**—Electrical, Optical, Mechanical, Chemical, Photographic, etc. Established 1862. Catalogues, 2d.—A. CAPLATZI, Chenies Street, Bedford Square. [18

**The Buyers' Guide to Books on Mechanical Subjects,** by English and American Authors, 6d. The best book on Lathe, with chapters on Screw-cutting, Metal spinning, 3s.; soiled copies, 2s. The latest and most complete Treatise on Screws of every kind, with numerous illustrations. English, American, Swiss, and French Threads, 3s.; soiled copies, 2s. Above are published and sold by BRITANNIA Co., Tool Makers, Colchester, and sent post free. [19

**Turning Classes or Turning Lessons.**—Those who would be willing to conduct evening classes; also those who can give instruction at their own house, are requested to forward their address, stating which they can undertake. —BRITANNIA Co., Colchester. Technical schools and workshops fitted up complete with tools, engines, shafting, etc. [20

**Model Ships' Fittings,** Model Engines, etc.—Catalogue, 70 illustrations, 4d.—STIFFIN & CO., 324, Essex Road, London, N. [1

**Paper Letters, Rubber Stamps, etc.**—Agents should apply for samples (free).—WILLCOX BROTHERS, 172 Blackfriars Road, London, S.E. [2

**Lettering and Sign-Writing made Easy.**—Also full-size diagrams for marking out eight alphabets only 1s. — F. COULTHARD, Darlington Street, Bath. Note.—100 Decorators' Stencils (60 large sheets), 2s. 6d.

**Fret, Carving, and Repousse Patterns.**—100 of either, full-size, 1s.; 300 Turning Designs, 1s.; 400 small Stencils, 1s.; 500 Shields, Monograms, &c., 1s., postage free.—F. COULTHARD, Darlington Street, Bath (late Bournemouth). [3

**Alberts,** white metal all through; warranted; 1s. 3d. post free.—R. HEAP, Castle Street, Southport. [4

**Cricket Tackle.**—Bargains; must sell. Four splendid all cane-handled match bats, grand driving blades, and worth 13s. each, price 7s. each; two best balls, 3s. 9d. each; set polished stumps, 4s. 9d.; pair leather wicket gloves, 3s. 6d.; pair batting gloves, 4s. 6d.; pair leg guards, 5s. 6d.; and handsome guinea Marylebone cricket bag, 10s. 6d., or if all taken, will accept £3 3s. All quite new, and approval before purchase.—SECRETARY, Bloemfontein House, Shepherd's Bush, London. [5

# A WONDERFUL MEDICINE.

# BEECHAM'S PILLS

Are universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, and all Nervous and Trembling Sensations, &c. &c. The first dose will give relief in twenty minutes. This is no fiction, for they have done it in countless cases. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

**Worth a Guinea a Box.**

FOR FEMALES THESE PILLS ARE

"A priceless boon, a treasure more than wealth; the banisher of pain, the key to health."

These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the nervous and debilitated is,

***BEECHAM'S PILLS have the Largest Sale of any Patent Medicine in the World.***

Prepared only by the Proprietor, T. BEECHAM, St. Helen's, Lancashire, in Boxes 9½d., 1s. 1½d., and 2s. 9d. each. Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

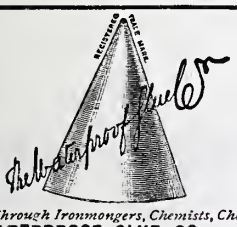
---

**FLUID WATER RESISTING GLUE** *(Patent)* **PATENT TINS.**

*Invaluable for all Out and Indoor Repairs.*

*Post, 8d. and 1s. 3d. per tin. Through Ironmongers, Chemists, Chandlers, &c., 6d. and 1s. per tin.*

Manufactured only by **THE WATERPROOF GLUE CO.,** 62, Dale St., LIVERPOOL.



**FLUID WATER RESISTING GLUE** *(Patent)* **PATENT TINS.**

No Brush—No Boiling—Will securely join Wood, Glass, China, Metals, &c.

Price 5d.

THE MOST PROFITABLE AND FASCINATING OF ALL HOME PASTIMES. EASILY LEARNT.

J. H. SKINNER & Co. having *Dissolved Partnership*, are offering their *Enormous Stock*, including 250,000 FRETWORK PATTERNS and 100,000 ft. of Solid and Three-Ply FRETWOOD, Veneers, &c.; 1,000 Gross of FRETSAWS, besides an immense quantity of TOOLS, OUTFITS, &c., as a special inducement to their customers to order at once.

**4,500 1s. Books of Fretwork Patterns**, each containing Twelve Large Sheets, beautifully lithographed, none of which would be sold retail at less than 2d., and many at 3d. and 4d. each; also

**1,200 2s. 6d. Books of Fretwork Patterns**, containing Twenty Sheets, 19 in. × 12 in., of new designs, many of which would retail at 6d. each. These Books,

**£375 in Value, will be GIVEN AWAY.**

Amateur customers ordering 5s. worth of designs from Catalogue will be presented with one of the above 1s. Books. Those ordering 10s. worth will receive a 2s. 6d. Book.

**An Allowance of 10 per Cent.** *in goods* will be made on all mixed orders for Wood, small Tools, Saw Blades, and Designs, amounting to 10s., and **15 per Cent.** on orders amounting to 20s. and upwards. NOTE.—*This reduction does not apply to Treadle Machines.*

N.B.—A SPLENDID OPPORTUNITY FOR BEGINNERS.

**Complete Fretwork Outfit**, comprising 12-inch Steel Frame, Forty-eight Saws, Awl, File, Four Designs (with sufficient Planed Wood and 1s. Handbook on Fretwork). **An Archimedian Drill,** with brass handle and Three Bits, will be **SENT GRATIS** with each Set. Post free for 3s. 6d. Outfits on Card, 1s. 6d. and 2s. 9d., post free. 6 ft. 2nd quality assorted planed Fretwood, 1s. 9d.; post free, 2s. 6d. 12 ft. ditto, ditto, 3s.; post free, 4s. 3d.

**SKATES!!!**—EVERY PAIR WARRANTED.—Sizes, 7½ in. to 12 in. No. 1, Unpolished Beech, 10d. per pair. No. 2, Polished Beech, 1s. 6d. per pair. No. 5, "Acme" pattern, all steel, 3s. per pair. No. 7A, "Caledonia" pattern, self-adjusting, one screw fastening the whole skate, the best principle, 6s. per pair. No. 8, Metal frame, with strap complete, 1s. 9d. per pair; postage, 5d. per pair. These are not rubbish; we warrant every pair.

NEW CATALOGUES of Machines, Designs, Wood, Tools, etc., with 600 Illustrations and full instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. A Specimen 6d. Fretwork Design **SENT GRATIS** with each Catalogue; also a List of Designs, Outfits, Tool Chests, etc., at Greatly Reduced Prices to clear.

N.B.—All orders *must* be accompanied by remittance. APPLY—

### A METAL CANOPY FOR BED HANGINGS.

BY J. WHITFIELD HARLAND.

MATERIALS — METAL PREFERABLE TO WOOD—THE DESIGN—WHERE TO OBTAIN THE PARTS READY MADE—HOW TO PUT THE FOUNDATION TOGETHER — HOW TO FIX THE STAMPED PLATES—HOW TO PROVIDE FOR FIXING TO THE WALL —COVERING THE "LAPS" OF THE PLATES AT THE ANGLES — KEEPING THE TUBES IN PLACE — THE VASES AND "DROPS"—CUTTING THE TUBES AWAY TO FIT FACE OF PLATES — GUTTA-PERCHA TEMPLATES — THE TWO END BAYS, AND HOW TO TREAT THEM—USE OF REPOUSSÉ WORK INSTEAD OF STAMPED WORK — CRESTING, CURTAIN-ROD, AND RINGS—VARYING THE COLOUR OF LACQUER—DRAPING.

ALMOST everyone is familiar with carved and gilt cornices for window curtains, and with the stamped brass imitations that have so much superseded them. The foundation of the window cornices, whether carved and gilt or stamped brass, is of wood, which in crowded cities and towns would not be advisable for bed canopies, as it would, especially from their comparatively inaccessible position, afford harbour for troublesome insects. It would therefore be far more cleanly, and sanitary also, to discard wood — which absorbs microbes in infectious illnesses — as a foundation, and construct the foundation entirely of iron. Wooden bedsteads have now almost disappeared, and metallic ones reign supreme. The bed canopy should naturally correspond and be of the same material, to be equally impregnable to vermin seeking refuge.

The perspective drawing (Fig. 1) shows an octagonal-shaped canopy made of stamped brass, lacquered and burnished, every part of which may be bought ready made from the furnishing ironmongers (those shown were purchased at A. Hawkins', London Road, S.E.), who usually keep several patterns in stock, and also have pattern-books showing hundreds of other

designs, which they will obtain from Birmingham if preferred to those they have. Anyone, therefore, wishing to make a canopy on the lines of the present construction is not obliged to accept any of the patterns here shown, but can select others according to individual taste.

In Fig. 9 I give one of these alternative stamped plates, Fig. 6 being the one I have used. These are drawn quarter full size—*i.e.*, the full size is 12 in. long exclusive of laps—and the price per foot lineal of Fig. 6 is 1s. 4d., or Fig. 9, 2s. 3d., and the "egg and tooth" moulding about 7½d. per foot run; so that the cost is very moderate. Six plates of each are required, so that 11s. 9d. covers that. The tubes for the corners, cresting, vases, and pendants, curtain-rod and rings, and the iron for the framing, with the flower pendants or the alternative bent tubes for the bays next to wall, would cost from 7s. 6d. to £1 more, according to the design chosen.

From the half plan, which is drawn to 1½ in. scale—*i.e.*, one-eighth full size—it will be seen that each bay is the length of the plates as sold—viz., 12 in. in the clear—and the tubes at each angle cover the joinings of the plates where they lap over, thus making a finish. Any of these parts not kept by the ironmonger can be had of chandelier makers.

For the framing, iron, preferably galvanised, ½ in. by ⅛ in., will be sufficiently strong, and consists of a flat back frame riveted together and the octagonal part riveted also to it. I have shown the back frame, *e e e*, etc., in Fig. 4, made of three pieces of iron, the upper one turned on an anvil so as to form top and sides in one piece, the two rails being riveted on the back of two sides in their proper position afterwards. My reason for this is that at the top corners not only must the octagonal upper rail be riveted to the back frame, but the fixing that is to carry the brass tube with the vase, v, must also be riveted thereto, so there would be *four* thicknesses to rivet together. I evade one of these, the lug of the fixing for the vase, by planting it on the end of the side of octagonal framing, and by making the back frame in one piece, avoid another of the thicknesses, so as to have only two to rivet together.

Having bent the three rails of the octagonal framing to the proper angles, which is best done by first making a template of ½ in. board cut to shape and battened, the ends for riveting to the back frame should be turned square of an L shape, about 1½ in. long, as in Fig. 11, which is an enlargement to quarter full size of the corner of back frame and octagonal framing, showing how they are to be joined together by rivets, and also how the lug of the vase fixing should be fixed.

When these three rails are fixed to the back framing, we have to arrange for the uprights at each angle (why should they not be called *downrights*, since the ideal of the canopy is inevitably that of suspension from the top member?). These may be made of one piece, bent to the section shown in Fig. 10, or of two separate pieces, each riveted to the rails, *a*, *b*, *d*, of the framing, one on each face of the octagonally bent rails. It is to these uprights, or "downrights," that the stamped brass plates are to be attached at their ends under cover of the, afterwards added, thin brass tubes at each angle. There are two ways of fixing these stamped plates: soldering to the tinned or galvanised iron framing, or, better still, riveting with copper rivets. I say better still, as the heating of lacquered brass by the soldering "bit" is very apt to discolour it beyond the limit covered by the brass corner tube, which would be very unsightly indeed. Two rivets at each end of each plate would be amply sufficient, or, as an alternative, the uprights could be drilled and tapped for small screws, which could be removed should the plates ever require relacquering, and be replaced very readily.

If in certain readily imagined circumstances difficulty in making the back frame is shown, small bolts and nuts might be substituted throughout for rivets, and the whole canopy could be taken to pieces, packed *flat* for travelling, and re-put together again whenever required. In this connection there is very little extra trouble in the substitution of small bolts for rivets, and it is evidently worth the difference to be able to take every joint asunder for cleaning, if not for transit; whilst the back frame could be then made of five separate pieces instead of being turned so that top and ends were in one piece as shown, as the bolts might just as well pass through three thicknesses as two, whilst riveting would not be good construction in such a case, although it might answer, as there is but little strain and but little weight to carry.

At *h* in the two drawings of the back frame is a hole of the form of an inverted keyhole—a provision for hanging the canopy to the wall—the circular part of the hole being sufficiently large to allow of a brass-headed nail passing through it, the slot above being as wide as the nail itself, so that when the weight causes the back frame to drop into its place, the nail-head prevents any tendency to slip forward. I prefer builders' "spout nails" to brass-headed nails, for they are stronger and more reliable, and are made specially to hold in the joints of the bricks of the wall without plugging, which offers harbour for insects.

Having completed the iron framing, the foundation upon which to build up the ornamental exterior, the next operation is to provide means whereby the brass tubes at each angle and the longer ones next the wall may be held in position. This may be done as shown by riveting, or by screwing to the uprights specially made fixings of the form shown in Fig. 11 (quarter full size), having a forged lug to a screwed end for the vases to be tapped to, and in Fig. 12 a similar one for the reception of the stamped pendants (which in the case before us are each made of the two stamped sides of gasalier weights), and these should be tapped to screw on to the screwed shanks fixed at the lower end of the uprights of the octagonal framing. Now, the diameter shown in the drawings for these thin brass tubes is about 1¼ in.; the screw for the vases and pendants is but ⅜ in. It follows, therefore, that a discrepancy or void has to be in some way made up in order to maintain the tube in position. I use "washers," 1¼ in., filed down to fill the interior of the tube, with ⅜ in. hole in centre, one at top and one at bottom of the tubes, the outer periphery of which enters the tube and prevents it moving sideways, whilst the hole in the centre fits the screwed shank and the vase in one instance, and the pendant in the other case, well screwed up, holds everything "taut," to use a nautical but expressive phrase.

It must be recollected that the tubes, as well as the stamped plates, are already

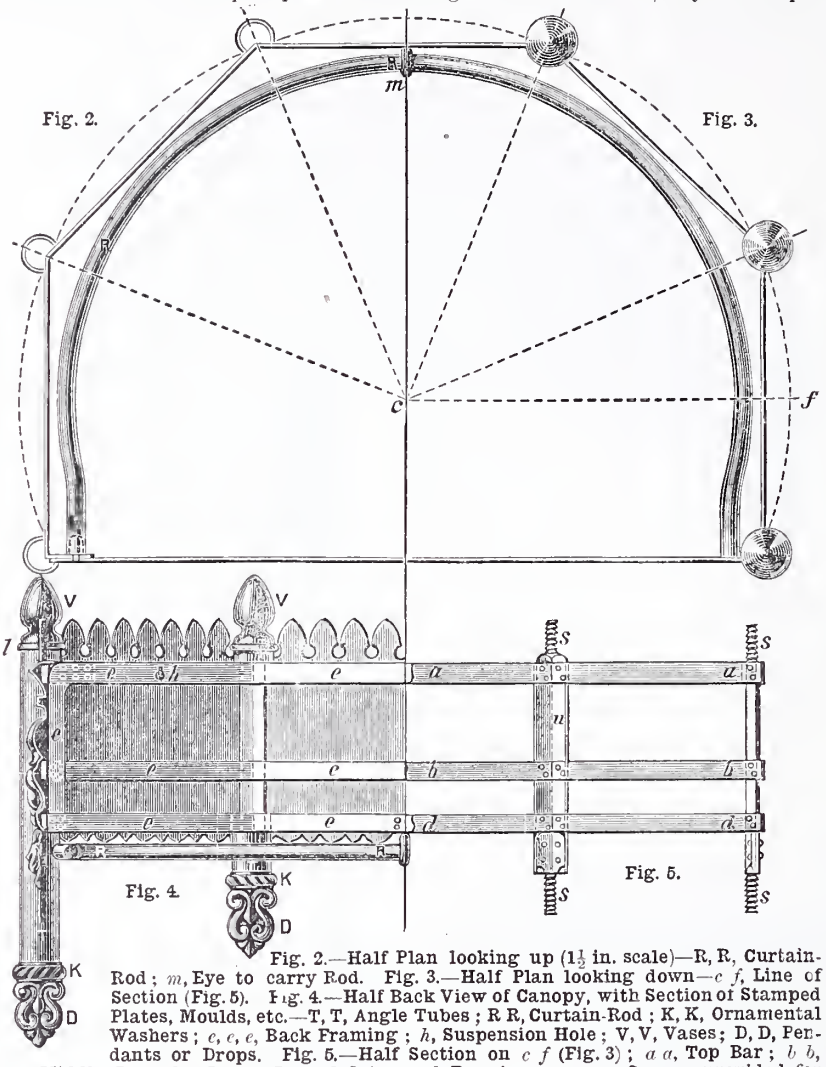

Fig. 2.—Half Plan looking up (1½ in. scale)—R, R, Curtain-Rod; *m*, Eye to carry Rod. Fig. 3.—Half Plan looking down—*c f*, Line of Section (Fig. 5). Fig. 4.—Half Back View of Canopy, with Section of Stamped Plates, Moulds, etc.—T, T, Angle Tubes; R R, Curtain-Rod; K, K, Ornamental Washers; *e*, *e*, *e*, Back Framing; *h*, Suspension Hole; V, V, Vases; D, D, Pendants or Drops. Fig. 5.—Half Section on *c f* (Fig. 3); *a a*, Top Bar; *b b*, Middle Bar; *d d*, Lower Bar of Octagonal Framing; *s*, *s*, *s*, *s*, Screws provided for Vases and Pendants (½ in. scale).

lacquered, and therefore we have to rely on the fitting, as soldering or running metal (lead) in is out of the question; but if care is taken to make the screws central, and the washers are made a "tight fit" in the ends of each tube, the tubes themselves can never even shake.

Hitherto the construction has partaken of the easiest, but we now come to the test—that pleasurable but difficult operation of fitting the angle tubes destined to cover the junction of the stamped plates.

The lengths of tube, cut off exactly the same, and filed finely to a perfectly square end, have now to be cut to the section obtained from the front face of the stamped plate which forms the various members of the canopy design. The tubes at ends, as shown, are intact, but in between they must be cut away from behind, so as to form a good joint against the face of the stamped plates already fixed to the foundation or frame which supports them in place.

Fig. 13 gives a profile of one of the tubes cut to fit the face of the plates whose joining the tube has to cover and conceal. This part of the business is the only difficult part of the construction, and affords therefore the most scope and the most delight in carrying it out. I presuppose that the rivets or screws have been put into the flat part of the stamped plates—*i.e.*, their lowest plane, which, of course is the nearest to the uprights of the framing—so as to avoid all bending of them out of shape.

A very easy dodge to make a template is to warm a piece of gutta-percha sheet at the edge and bed it firmly to the stamped plate till it takes the exact form, and when it is cool and hard again you can scribe the tube to the exact line you require. The tubes shown here are plain burnished thin brass tubes, but they may be had covered with pattern, ribbed, spiralled, or to almost any imaginable design, and of larger or smaller diameter. I never like to tie anyone down to following slavishly any design for construction; I prefer infinitely to suggest as many other ramifications of the idea as I can. When a man takes pains and trouble to make any object for his own home, its possession gives him many times the pleasure if it be unique of its kind and design than if, as is too often the case with bought fretwork patterns, he can see it carried out in fifty different homes just as he has himself done it; and for this reason I endeavour to give alternative modes of carrying out my ideas.

I have throw out the hint that instead of purchasing ready stamped plates, lovers of repoussé work may indulge their proclivities in their own peculiar way, and thus produce a much more elaborate and beautiful, and far more valuable, piece of canopy-work than the cheap though effective suggestion of the present paper. In such case the two bays or panels next the wall might be treated differently to the others, and the centre front one could be altered to suit, thus getting rid of what I confess is the drawback in my present design—its formality as a whole, necessitated by utilising what is already in existence instead of being specially designed and made expressly.

Having cut the tubes to fit against the face of the plates, and then put them into place, so as to cover up the joinings or laps of the plates, the ornamental rings at K, K, *l*, *l*, which form a finish to the ends of the tubes and conceal the supporting washers, should be next fitted. It must be borne in mind that the fixing to carry the pendants should not be riveted to the framing until the tubes and these ornamental rings are fitted, as it would not be possible to get the tubes on after these were once fixed, as is self-evident. For this reason, instead of riveting, screwing them on to the frame from the inside would be better—an operation that would thus be much more easily performed.

In order to maintain the rigidity of the octagonal framing, a round rod at the centre line should be inserted from one top rail to the other, which should be filed down a little to fit a hole drilled in each smaller than its diameter, and passed through and riveted at each end. Immediately under this rod, at the point *c*, the curtain material could be plaited in rays and stitched round the rod, thus forming a centre concealed by a covered button, if desired.

The curtain-rod itself consists of a length of brass tube bent to the shape shown, and passed through an eye which is riveted to the framing at *m*, the centre of the front lower bar of the frame, and sprung on to pivots or studs at each end, which have been tightly screwed previously into the lower bar of the back frame. Enough spring can be obtained by not bending the tube quite far enough for the width apart of the studs to maintain it normally in position, yet allowing of its being taken off at will to permit of the rings coming off with the curtain to be washed, if washable; if not, of brushing, or, if need be, re-dyeing them.

The back cloth should be plaited to a tape the same length as the top back frame rail, and two small rings which would pass over the screw below the neck of the vases next the wall before they were screwed down would form a convenient mode of fastening each end of the tape, and keep it stretched tightly across.

The curtains should each be a yard and a half wide, box-plaited to a tape to which the curtain-rings could be attached either by pin-hooks or by the ordinary stitching with strong thread, and hemmed at the bottom, and either with or without fringe. No cloth valance is required, but if preferred, it could be readily fixed with tape ends or strings to tie round the lower bar of the octagonal framing to conceal the curtain-rod and rings, as the plates when fixed leave an interstice between themselves and the frame bars, being fastened to the uprights which are planted on to these bars.

The cresting, which may be cut out of thin sheet brass, should be turned up ⌊ shape at lower edge to its inner side, so as to stand and rest upon the top of the upper member of the cornice, to which a couple of copper wire rivets in each length would conveniently attach it; or eyes could be cut at each end of each length to pass under the vases on the ⌊ flange, which is turned under, going round the screws that fix the vases, thus holding it firm at ends.

In the end bays next the wall, to overcome the stiffness and formality of the straight cornice dying into the tube, either a tube bent round as shown in the perspective view (Fig. 1), or a stamped flower finial, should be added, fastened with small screws to the endmost tube, which it will be seen is left longer than the other four. These end bays are simply to be considered as brackets, and should fulfil this idea of supporting the projecting canopy. This completes the construction.

Various modifications may be made, according to individual taste, either in the form of the design or in the colouring of the lacquer. For instance, the plates (Fig. 6) may be of rich gold, whilst the upper member (Fig. 7) might be lacquered Florentine bronze colour or dark green; and the colour also of the tubes could be varied if preferred; and no doubt other alternatives will suggest themselves.

## A USEFUL RIMER OR BROACH.

BY T. R. BLACKETT.

Sketch of Tool—Its Cutting Edge—Example of its Use—Economy of Tool.

The sketch given here will be enough to the skilled mechanic to grasp the use for which it is intended, but for the sake of our readers in general I will give a full detail of its uses.

The sketch is of a rimer, or broach, as some call it, screwed at the end. Take, for example, that the tool is for a $\frac{7}{8}$ in. hole. The screwed end is to be screwed with a good $\frac{7}{8}$ in. Whitworth thread, say, up to $\frac{7}{8}$ in. from the end; here to have a shallow recess $\frac{1}{4}$ in. wide, according to sketch; then to be squared down with a side tool in the lathe $1\frac{1}{8}$ in. from the end. This forms the cutting edge of the rimer. The rimer part of the tool, while it is being forged, must be kept large enough to be filed up in cants, whose section must be in the form of a

**Form of Rimer or Broach—A, End View at A'; B, End View at B'; Screw, $\frac{7}{8}$ in. Whitworth Thread.**

pentagon or five-sided figure. This can be carried up for, say, a couple of inches, and to be large enough to rime a hole out which will nicely fit the unscrewed part of a tap bolt or turned stud.

Now to its use. Supposing we have to fix the pedestal of a governor on to the bed-plate of an ordinary horizontal engine. The foot of the pedestal having been drilled to suit the $\frac{7}{8}$ in. studs by which it is to be bolted to the bed-plate, and as its pulley has generally to be parallel with the engine crank shaft, we set it in that position and mark with a scriber through the holes in the foot of the pedestal. The holes in the bed-plate are then drilled with a ratchet brace and a drill that will just go into an ordinary $\frac{7}{8}$ in. nut; these holes are then tapped.

Now, if we were to put the studs into their places and try our pedestal on, we would find in nine cases out of ten that we were a *very little* out. It is to rectify this error that this tool is intended.

We now place the pedestal on the bed-plate in the position in which we marked the holes. Take two old tap bolts, with their unscrewed parts filed down level with the threads so as not to touch the pedestal; these, if placed in the opposite diagonal corner holes and screwed down tight, will hold the pedestal steady. Now take the tool and screw it down the other two holes until the face at B comes through the pedestal and touches the bed-plate. Having done this, take off the pedestal, and put in the two studs (where we have had the tool); then do the same with the other two holes, put the studs in, and the job is finished.

There will be no cause to fear the possibility of the pedestal shifting by the wear and tear of its working; it will be too good a fit, and exactly parallel with the crank shaft as required.

To make such a tool or set of such tools screwed to suit the different sizes of studs, would save time, money, and trouble in the majority of cases.

For instance, a tap bolt has to be screwed into a job in a hurry. Well, the hole in the flange through which it has to go is found to be a *shade out*. It would be better just then to put a tool through of the proper size, then put in the tap bolt as required.

If we had not such a tool, we would have to take the whole job down and file the hole out, thus taking, perhaps, four times the time, not making such a good job of it, and losing a lot of patience.

This tool, of course, must be made of tool steel, kept soft until it is filed up, and then to be tempered.

[The name of the tool described above has been here given as "rimer." To save any reader the trouble of writing about it under the supposition that it is a blunder, let me say that it is generally spelt "reamer," and that this is really the right way of doing so. But it is spelt in many different ways by engineers, and usage renders "rimer" or "rhymer" as admissible as "reamer."—ED.]

thickness which the ends of the staple penetrates the firmer will the staple probably be), cut it to the desired thickness, as in Fig. 46. A pair of discs will be also utilised. These will fit securely on to a handle, as in Fig. 46. The distance between the wheels must be exactly the same as the thickness of the staple, and the diameter of each should nearly correspond to the width of it. Over that part of the handle which lies between the wheels will be screwed a piece of tubing or turning, sufficient in diameter to allow it to touch the inner edge of the staple.

The wheels might be turned from a piece of hard and tolerably thick wood, but it is advisable that the staple be of iron.

Completely through the wheels, etc., should be bored a pair of holes, close up against that part of the handle which penetrates them, each hole being in diameter sufficient to be capable of receiving the largest gauge of wire that it is considered will be used. In Fig. 47 is shown an elevation, by the assistance of which my foregoing remarks may be the better conveyed in an understandable manner.

by reason of the natural shortening of the wires.

Were the first requirement ignored, the liability remains of the wires going on excursions every now and again to either side of the imaginary straight line upon which they should travel; and in the case of the latter consideration being disregarded, it would frequently be found that the weight would appear rather dilatory by remaining where it was at first placed and allowing the wires to be drawn from underneath it.

To those who desire to be nice in everything they do, my advice is to insert a metal plate flush with the top of the bench upon which the wires will twist, or to at least work upon a part of the bench which may be comparatively smooth.

It is astonishing what can be accomplished by the aid of a machine such as I have just been describing. If proper judgment is exercised in the selection of the weight, and due care is taken in having the machine to fit nicely together in all parts, and, in addition, the work is progressed with upon smooth ground, by rapidly turning the handle for a few moments, several yards of

Letters in Diagrams represent Correspondence of Parts.

## WIRE-WORK IN ALL ITS BRANCHES.

BY JAMES SCOTT.

### Twisting—A Twisting Machine.

Staple of Machine—Staple fitted to Bench—Discs or Wheels—Handle—Wheels, how Placed—Weighting Free Ends of Wire—Metal Plate on Bench—Rapidity of Work.

Twisted wires are utilised to a very great extent as being capable of producing better ornamental effects upon any particular work in which they may be introduced, and certainly they are to be preferred, in a number of cases, to merely plain or straight wires.

It is my intention to give, later on, designs of such articles in wire-work as I may consider sufficiently serviceable to warrant their publication, and in some of these patterns I shall represent twisted wires.

A glance at Fig. 46 will be necessary to understand one method, which is as convenient as any other, of thus twisting two wires; or, what amounts to precisely the same thing, one wire doubled together. A staple of stout iron with spiral ends is required, and nuts to screw on to the ends of it. This staple is fitted to the bench, and I must here say that should the latter be considered too thick (although the greater the

The wheels, etc., are placed underneath the staple so that they may be turned freely by means of the handle attached. The ends of the wires to be twisted should be placed through the holes in the wheels, from the bench side of them, and then tied. If they are short it will be only necessary to work at the side of the bench, but if the wires are of any great length it will be expedient to work from the end. It will, therefore, be understood that it is advisable to have a pair of staple holes at both the side and the end of the bench, to be made use of when occasion arises.

The free ends of the wires should then be placed side by side flat upon the bench, or else tied in a clean knot. Upon this end of them must be a weight, and experience will be the only adviser as to the heaviness of it. The handle is then turned, the consequence being that the wires are twisted to a certain degree, the natural result being to shorten the distance in the length occupied by the pair.

It is upon this that the heaviness of the weight just alluded to must depend. It is required to be of sufficient pressure to keep the wires in a perfectly straight line whilst being twisted, and also to be not too heavy to permit it to advance towards the staple

wire may be regularly twisted. To gain an idea of the relative proportions of twisted and untwisted wires, it is necessary only to take a couple of wires, each a yard in length and of thin gauge, and twist up to the utmost limit, and a couple of wires of thick gauge, of the same length, also treated similarly.

## KNOTTING, SPLICING, AND WORKING CORDAGE.

BY LANCELOT L. HASLOPE.

### Ring Knots.

Slippery Ring Knot—Boat Knot—Lark or Double Boat Knot—Lark's Head—Lark's Head Stoppered—Lark's Head with Crossed Ends—Double Lark's Head—Treble Lark's Head—Backhanded Sailor's Knot—Capstan Knot—Sailor's Knot—Gunner's Knot—Artilleryman's Knot.

We have very commonly to make a rope fast to a ring, and there are a variety of methods of doing so, some of them identical with knots used for other purposes; but as they have their own names, I have thought it best to give them here. Fig. 43, where the end is passed through the ring, and a bight put under the standing part, is a ready way

of temporarily fastening the painter of a boat to the ring of a pier; as in the Stationary Knot, a sharp pull at the end of the rope frees the painter at once. This is an excellent fastening for many purposes. Fig. 44, called the "Boat Knot," is another good way of mooring a small boat. It is made in the same way as a Marlinespike Hitch, the only difference being that a thowl pin or other small piece of wood is put through the centre of the knot instead of a marlinespike. By withdrawing the pin a bight through the ring, and drawing the two parts of the rope through the bight; or where this is not practicable by reason of one end of the rope being fast, the end may be passed up through the ring behind the standing part, and down through the ring and bight again. Sometimes, instead of stoppering this knot with an overhand knot, as in Fig. 47, we seize the end to the standing part with twine or other small stuff.

Fig. 48 is a "Lark Knot" with crossed ends, and is made in the manner I have described, where one end of the rope is fast, except that the end at last comes over instead of through the bight. The ends are often stoppered as in the last knot. If we take the standing part in one hand and the end in the other, and draw them apart, we shall find, though with a name of its own, this is really nothing more than a "Clove Hitch" or "Builder's Knot" under a different name and different circumstances.

In the "Double Lark's Head" (Fig. 49) a bight is first made, and the ends passed through it; the ends are then put through the ring and through the loop just made and hauled taut. In Fig. 50 we have the "Treble Lark's Head," which, though it looks complicated, is more easily made than its appearance would lead us to expect. First bring the bight of a rope up through the ring, take one of the ends, and pass it through the bight, and up through the ring, and then down through its own bight; do the same with the other part and the knot is formed.

In Fig. 51 we have a "Backhanded Sailor's Knot." It is made by passing an end through the ring round at the back of the standing part and through the ring again, and finishing with two half-hitches round the standing part. It may also be made with the end in the last turn put under the standing part and under its own part. Fig. 52 is the "Capstan Knot." Cross the end of the rope after it is through the ring, bring it round the standing part, through the first bight and through its own bight, thus forming a sort of figure-of-eight knot.

Fig. 53 is a "Sailor's Knot," composed of

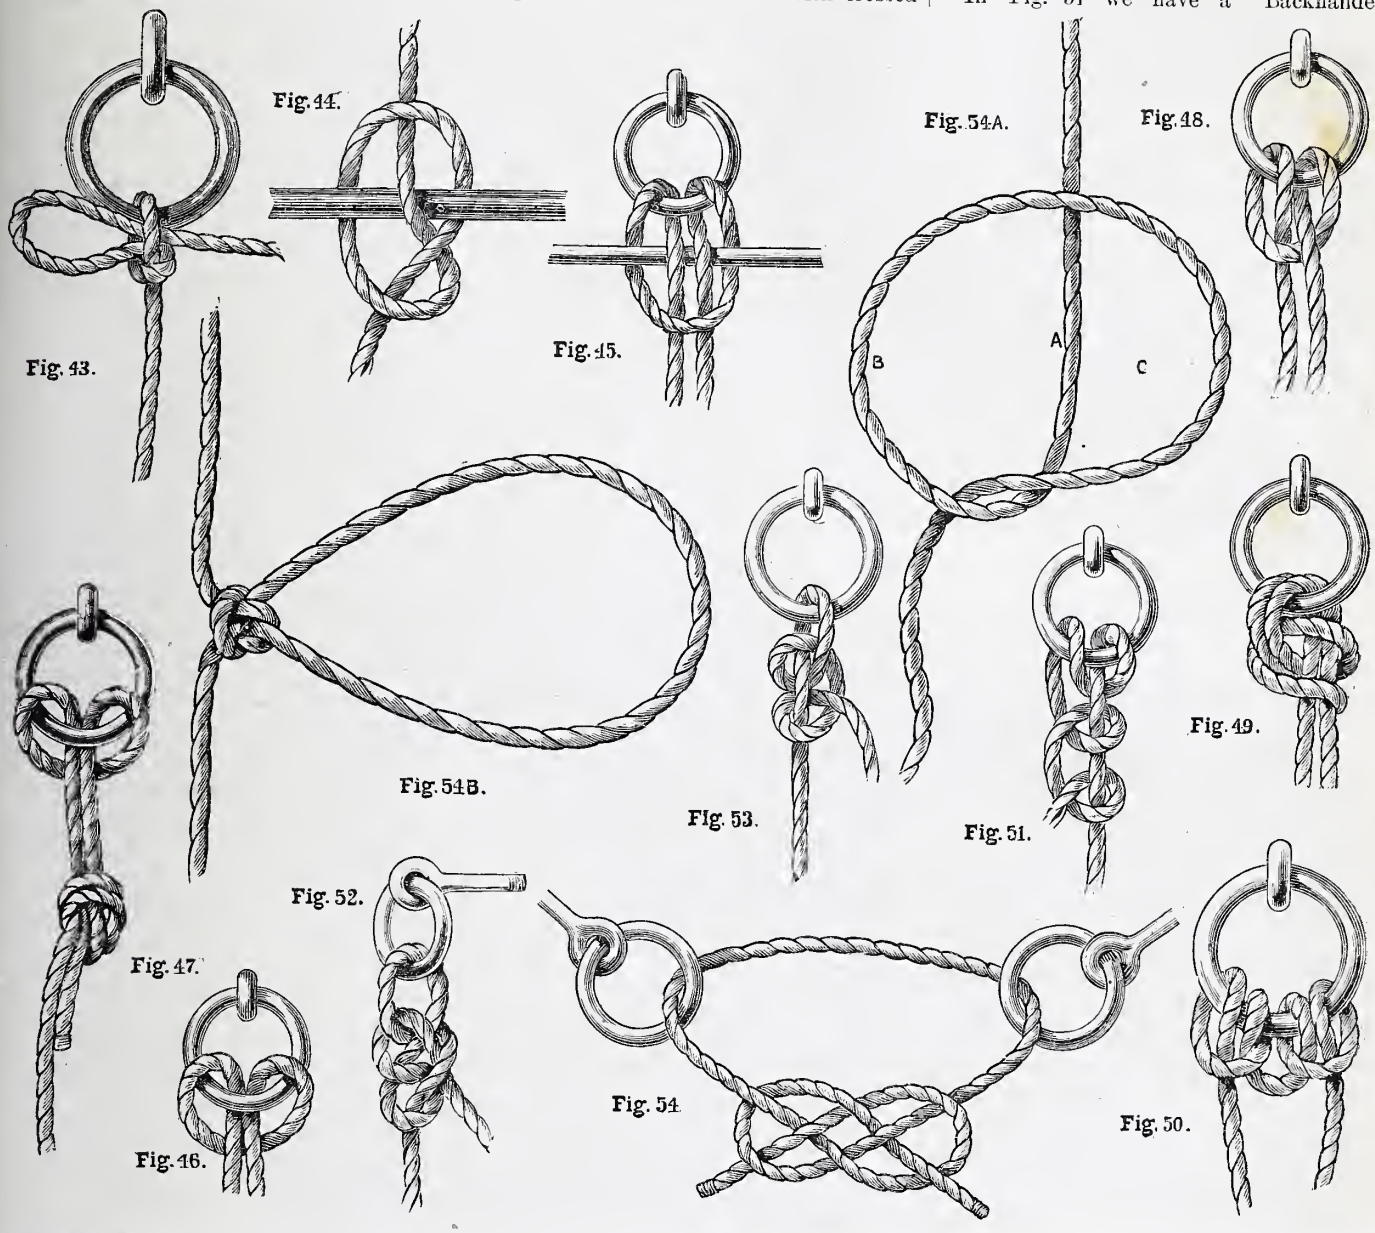

**Fig. 43.—Slippery Ring Knot. Fig. 44.—Boat Knot. Fig. 45.—Lark Boat Knot. Fig. 46.—Lark's Head. Fig. 47.—Ditto, Stoppered. Fig. 48.—Ditto, with Crossed Ends. Fig. 49.—Double Lark's Head. Fig. 50.—Treble Lark's Head. Fig. 51.—Backhanded Sailor's Knot. Fig. 52.—Capstan Knot. Fig. 53.—Sailor's Knot. Fig. 54.—Gunner's Knot. Fig. 54 A.—Artilleryman's Knot commenced. Fig. 54 B.—Artilleryman's Knot finished.**

the knot comes adrift of its own accord. Fig. 45 is another form of boat knot, called the "Lark Boat Knot," or "Double Boat Knot." This differs from the last knot, inasmuch as a bight, instead of a single end of rope, is put through the ring; a piece of wood is used to fasten it, as in the Boat Knot. It is rather the better knot of the two. If, instead of the ends being brought down outside the bight after it has been passed through the ring, they are put through it, we have a "Single Lark's Head" (Fig. 46), and in Fig. 47 we have the same knot "stoppered." It may be made by passing

two half-hitches round the standing part of the rope. This is one of the most useful and easily-made knots we have, and is very much used as a mooring knot.

A "Gunner's Knot" (Fig. 54) is simply a "Carrick Bend," made with the two ends of a rope after it has been passed through two rings. Gunners themselves call this a "Delay Knot."

The knot shown in Figs. 54 A and 54 B is called "Manharness," or the "Artilleryman's Knot." It is used when hauling guns over a difficult country, when horses cannot be employed to get them into position. It is a most valuable knot where heavy weights have to be drawn with ropes, as by its use a man can exert his strength to much greater advantage than he could by merely grasping the rope with his hands. To make it, form a half-hitch, turn it round, and lay it against the standing part. This is, in fact, a Marlinespike Hitch, and is represented in Fig. 40 (page 200). Now pass the right hand into the bight C, and going under A, as shown in Fig. 54 A, grasp the part B, and draw it through C until a loop of sufficient size is made. When using it, the head and one arm are passed through the loop, as shown in Fig. 54 B, which gives the knot finished. A little care is required in closing the knot, so that the turns may jam properly one against the other, or the knot will slip.

When several men are employed, a bowline is generally made at the end of the rope, and as many loops as there are men to haul at equal distances along it.

## CAST-IRON COLUMNS.

BY G. H. BLAGROVE.

FORM OF HOLLOW CYLINDER ECONOMICAL—OBJECTION TO FORM—TESTING METAL AND THICKNESS — BASE-PLATES — BED-STONES — FIXING COLUMN AT BASE—BOLT-HOLES—SEATING—STRENGTH OF CAST-IRON COLUMNS—ESTIMATES—PRICES.

IT is generally admitted that the most economical form for a column is that of a hollow cylinder. What we require in a column is that it shall not bend; and if we can ensure this, it will safely resist any crushing strain likely to be brought upon it. The greater the diameter of the column in proportion to its length, the greater will be its resistance to bending. This may be illustrated in the case of a cane, which is bent by a person leaning upon it. The material on the inside of the bend is compressed, while that on the outside is stretched. The greatest deflection occurs midway in the length of the cane, where the greatest tension and compression of the material occur. In a cross-section of the cane at this point there would be a neutral line running at right angles to the direction of the bend, where the material would be neither stretched nor compressed. The neutral line would probably be near to the centre of the cane, but its position would depend upon the nature of the material. If the latter were more easily stretched than compressed, the greater proportion of the cane would be subjected to tension, and the neutral line would be nearer to the inside of the bend. This neutral line may be regarded as the fulcrum upon which the two half-lengths of the cane turn like levers, the fibres of the cane being stretched or compressed according as they are situated on one or other side of the fulcrum. The distance of any single fibre, measured at right angles to the neutral line, may be regarded as the short arm of the lever; and the greater that distance is, upon the well-known principle of the lever, the greater resistance is opposed to the movement of the long arms. Hence, a cane of the same sectional area, but hollow, and, therefore, of greater diameter, would be more difficult to bend, because its material would be concentrated further from its axis. Upon this simple principle of leverage depends the truth of that theoretical formula, according to which the strength of a column varies directly as the fourth power of its diameter, and inversely as the square of its length. True as it is in theory, it is only partially true in fact; for the theory assumes that a column yields entirely by bending, whereas experience has shown that it yields partly by crushing also. Hence formulæ are employed in practice which have been modified to bring them into accordance with the results of actual experiments.

The only objection to the hollow cylindrical form for a cast-iron column lies in the difficulty of examining the inner face of the metal, and of testing its thickness. If proper precautions are taken, however, there is no reason why a hollow cylindrical column should not prove as satisfactory as any stanchion of open section. As regards the soundness of the metal, hammering affords a reliable test, and the thickness can be measured with callipers. An easier and more satisfactory method of testing the thickness is available when the core of the column runs through from end to end; for then rods can be held against the metal inside, and measurements can be taken to these rods from the outside. Even when a girder is to be carried upon the column, and a boxing is cast on to receive it, the core may run right through the column. The circular piece of iron omitted from the cap-plate would be of no utility in transmitting pressure from the girder to the column. What is wanted is that the bottom plate of the girder shall cover as large a proportion of the section of the column as is possible. As a rule, the process of fixing is greatly facilitated when boxings for girders are cast separately; and the additional cost which this involves is very trifling.

The sizes of base-plates should be arranged in proportion to the loads upon columns, and to the carrying power of their bed-stones. When we know the diameter of the column, and the load which it is to support, we must devise a base-plate large enough to distribute that load over a sufficient area to avoid cracking the bed-stone beneath. If the base-plate be square, and its diameter twice that of the column, the proportion will be just about right, as can be proved by a simple calculation. To take an extreme case, we will assume a 9 in. column of ½ in. metal, which will give about the smallest sectional area in proportion to the diameter that is safe or usual in practice. The sectional area will be 13·35 square inches; and as the safe load upon cast iron does not exceed three tons per inch, our maximum load in this case will be just forty tons. If we make our base-plate 18 in square, it will, if solid throughout, have an area of 2·25 square feet. But we must deduct from this the bore of the column, which is 50·27 square inches, with an additional 4 in. for bolt-holes, making 54·27 in., or ·36 of a square foot, in all, which deduction leaves 1·89 square foot for the actual area of our base-plate. This is the area over which the forty-ton load will be distributed, and it works out at the rate of 21·16 tons per superficial foot. If the bed-stone be of good hard Yorkshire stone, it will safely stand a pressure of twenty-five tons to the superficial foot; and if of granite, it will stand forty. The base-plate should be of the same thickness as the metal of the column. The metal should spread from the column to the base-plate in a trumpet-shaped manner, the column being slightly thickened towards the base, and the base-plate being similarly thickened near its junction with the column. The object of this spreading and thickening is, of course, to provide adequately for transferring the pressure from the column to the base-plate; but the change of thickness in the metal must be brought about gradually, to avoid any danger from the unequal cooling of the casting. Some portion of the upper surface of the base-plate will, therefore, have a slight slope. The distribution of the pressure from above can be greatly assisted by means of gusset-pieces, of the same thickness as the metal of the column, and uniting the column to its base-plate. If bolts are used for fixing, there can only be four of these gusset-pieces abutting upon the four sides of the base-plate.

With regard to the fixing of a column at its base, this has sometimes been done without bolts, by means of lugs cast on to the underside of the base-plate, and let into holes sunk in the bed-stone. One advantage about dispensing with bolts is that diagonal gusset-pieces can be cast on, which is desirable when the load to be carried is considerable. But lugs, besides being liable to break off, do not afford such a secure fixing as bolts; and if lugs are used, it is advisable to form a square sinking, about half an inch deep, in the bed-stone, of the same size as the base-plate, to receive the latter, and preclude the possibility of its shifting. If bolts are used, this sinking need not be provided. There is no necessity to run the bolts right through the bed-stone, and provide them with heads and washers on the underside, as is sometimes done, for there will be practically no tensile strain upon the bolts. A good fixing may be obtained by sinking lewis-holes in the bed-stone, and letting in lewis-bolts. If the surface of the base-plate slopes where the bolt-holes occur, level seatings, or flanges as they are sometimes called, should be cast for the nuts; otherwise, it will be necessary to provide bevelled washers, which will involve some extra labour in filing.

Bolt-holes may be either cast or drilled. Of course, it is cheaper and more expeditious to have them cast. There is no objection to casting the holes in a base-plate which is to rest upon a bed-stone, or in a cap-plate to which the flange of an iron girder is to be bolted, the holes in the flange of the girder being drilled or punched. But when the bolt-holes are cast in two castings which have to be bolted together, one above the other, the iron may shrink unequally, and the holes will not be plumb over one another. In such a case, therefore, the bolt-holes, or at least one set of them, should be drilled.

All seatings, such as base-plates and cap-plates to columns, should be planed true, as it is difficult to ensure absolute freedom from slight irregularities in castings. Very slight irregularities will often suffice to produce grave results, by concentrating the pressure upon a few points, instead of letting it be distributed over a whole surface. All bearing surfaces should be packed with lead or felt, to prevent unequal pressure as far as possible.

The ultimate strength of cast iron in columns is found by experiment to be, for every square inch of sectional area, 28·5 tons at ten, and 17·8 tons at twenty diameters high. At about twenty-five diameters high, the strength is thirteen tons per inch, at which limit built columns of wrought iron have the same strength, and beyond which wrought is superior to cast iron. The safe load should be one-tenth of the ultimate strength; and it can be ascertained at a glance from those very useful tables for engineers which are issued by Hurst, Molesworth, and others.

In making estimates for cast-iron columns, the tables published in the above-named pocket-books will furnish the practical man with all that he requires. For instance, if we want a column 10 ft. high to carry a load of forty tons, we shall find that the external diameter will be 8½ in., and the metal ¾ in. thick. A table gives us the weights, per lineal foot, of cast-iron pipes, and the pipe we want is of 7 in. bore and ¾ in. metal, weighing 57 lbs. per lineal foot. Our column, therefore, weighs 5 cwt. 10 lbs. We must add a cap and base-plate, each 17 in. square, ¾ in. thick, weighing, at 28⅓ lbs. per square foot, just 1 cwt. By not deducting the bore of the column from these plates, the surplus will allow for the spread of the metal and for gusset-pieces. The total weight of the column will, therefore, be 6 cwt. 10 lbs., and its cost, at 10s. per cwt., will be £3 1s.

The price taken for the iron would include fixing, but an allowance should be made for the bolts. Four of these will be required for fixing the base-plate, and they may be of 1 in. diameter, and each 5 in. long, weighing, at 2⅔ lbs. per foot, just 4½ lbs. Four hexagonal nuts, at 1¼ lb. per pair, will weigh 2½ lbs., bringing the total up to 7 lbs. for bolts and nuts, which, at 4d. per lb., would cost 2s. 4d., bringing the cost of the column and bolts up to £3 3s. 4d. If four more bolts were required for attaching the cap-plate of the column to another casting above, these could be each 4 in. long, weighing 3½ lbs.; they would have hexagonal nuts, weighing, at 1¼ lb. per pair, 2½ lbs.; and square heads, weighing, at 1¼ lbs. per pair, 2½ lbs.; bringing the total up to 8⅔ lbs., which, at 4d. per lb., would involve an additional cost of 2s. 11d.

## NESTS OF ENCLOSED PIGEON-HOLES.

BY C. E. MAES.

DOORS AND REVOLVING SHUTTERS—NEST WITH TWO DOORS—VARIOUS MODES OF HANGING DOORS—DOOR FOR WRITING PURPOSES—SMALL NEST—CONSTRUCTION AND FITTING OF SHUTTER—GROOVES—SHUTTER WOOD—VARIOUS BANDINGS—ALTERNATIVE CONSTRUCTION OF SHUTTER—FASTENING THE SLIPS OF SHUTTER—FIXING THE SHUTTER—NEST WITH DOUBLE SHUTTERS OPENING TOWARDS ENDS—DOUBLE BACKS.

I HAD recently the pleasure of directing readers of WORK how to make a simple nest of pigeon-holes for the classification of letters and other papers. The one described was open in front, so that the contents could not be regarded as secure from the prying eyes of curiosity. This in many instances might be undesirable, for there are few of us who have not some correspondence which we wish to keep private, and apparently this fact has occurred to others, for it has been suggested that the article alluded to should have a sequel giving directions for the construction of a nest of pigeon-holes, the contents of which can be secured under lock and key. In the interest of "my masters, the public," who are readers of WORK, I hasten to comply with what appears a reasonable request, and must, in order to avoid going over the same ground twice, refer those who want information about making the pigeon-holes themselves to pages 103 and 104 of this volume of WORK. The remarks in the present article will be confined to such alterations as may be necessary in connection with the construction and arrangement of doors and shutter fronts.

As shutter or revolving fronts entail a good deal of extra work, it may be well to suggest, for the benefit of those who either have not the time or the desire to take more trouble than is necessary, that a plain hinged door or doors may be used instead of the revolving front, and a few directions regarding the doors and their general arrangement may not be amiss. As this article, however, principally deals with the other method of closing, much space cannot be devoted to the subject of doors, which I may take for granted the reader knows how to make. Detailed directions for their construction may therefore be regarded as unnecessary, and a few remarks in connection with their adjustment to the nest must suffice.

Doors may be added to the nest of holes, made exactly as previously described, by fastening the hinges to the front edges; but this would, at the best, be a somewhat clumsy arrangement compared with the alternative mode of hingeing the doors within the ends, so that the fronts of the doors are on the same level as, or, better still, a trifle back from, the edges of the ends, top and bottom. In order that they may be so, it is only necessary to have the partitions and shelves shallower from back to front than the outer casing—to at least the extent of the thickness of the door framing, which may be about ¾ in. On the left-hand door a bolt will have to be fitted, shooting into either the top or bottom of the case, or, if preferred, two bolts shooting into both may be used. On the right-hand door a "cupboard" lock with bolt shooting to the left will be fixed. The nest of pigeon-holes so made will resemble Fig. 1, which, it will be observed, shows no superfluous ornamentation in the way of mouldings, beadings, etc. These can be added according to the taste and skill of the maker, but, it will be noted, do not enhance the value of the nest so far as mere utility is concerned in the smallest degree.

For a small nest possibly one door may be preferable to two, but this the intending maker must decide for himself. It may, however, be suggested that in a long, low nest such as that described in the previous article, if one door is preferred, it will be better to hinge it at the top or bottom rather than at the end. If hinged at the top, a stay of some kind will be advisable to keep it open when the contents are being got at. This arrangement, however, will be more awkward generally than if the door is hinged at the bottom. In this case the door remains open by its own weight, and, if not allowed to hang down, forms a convenient table on which to sort or look over any of the contents of the holes. It will no doubt occur to many that the lid in this position may very easily be used as a writing table, in which case, of course, the panel and framing must be flush on the inside, and will be pleasanter if lined with cloth or leather. To prevent the lid, or, as we may now call it, the table, falling further than required, a joint stay, obtainable at any cabinet brass shop, may be used, or a simple chain or cord fastened to the inside of the lid and inside the ends.

Many of those who intend to use the inside of the lid for writing purposes may think that if part of the space occupied by the pigeon-holes were devoted to stationery—such as note-paper, envelopes, ink, pens, etc.—it would be an improvement. If they do not quite see their way to effecting this, perhaps Fig. 2, which shows the nest with the lid down and part of the interior arranged as suggested, may be useful to them. They will also notice that this illustration gives an idea by which the article may easily have a more ornamental appearance given to it. In fact, the plain nest of pigeon-holes has become a sightly piece of furniture, which, if carefully made, would not be out of place in any library, and is worthy of being made in better wood than pine, which, however, will do very well for the shelves and partitions.

Now let us turn to the construction of a nest with shutter or revolving fronts. I daresay it is well enough known that in this form of enclosing the contents, doors opening in the ordinary way are not used—if they can be called doors at all; they slide, and, in order to turn corners, they are flexible. They are formed of narrow strips of wood, fastened close together on a canvas or other suitable backing, and slide in grooves prepared for them. Before, however, giving directions for the construction of the shutters, it will be well to take the opportunity of describing a smaller form of a nest of pigeon-holes, and one which will probably be at least as useful as the larger one for ordinary domestic use.

As will be seen from the illustration, Fig. 3, it is rather higher than wide, and is divided into sixteen holes, in four rows of four. The extra height is not only that the shape of each hole may be more sightly and convenient than if square, but is owing to the fact of there being what may be called two tops to the case—one of them the outer one, and the other immediately above the pigeon-holes. Between these two tops is a vacant space of some three inches, to hold the shutter when it is raised as it is shown to be partly in the illustration last referred to.

A suitable size for such a small nest of pigeon-holes may be named as about 1 ft. 8 in. high, 1 ft. 4 in. wide, and of, say, 10 in. in depth, from back to front, outside measurements. Of course, these may be varied to almost any extent to suit particular purposes, and the only point in connection with them to which it may be necessary to call attention is the depth from back to front *inside*. As the pigeon-holes must be set back to allow of the shutter working in front of them, see that they are deep enough to hold any papers intended for them—in other words, the shutter should clear the papers.

As may readily be imagined, the shutter slides in grooves in the sides or ends of the case, so that, in setting out these, both the thickness of the wood forming the sliding front and the width of the groove will have to be considered with regard to each other. For a small or ordinary sized nest, such as has been referred to, ordinary ¼ in. stuff will be amply thick enough for the front, although, as even the veriest tyro will know, it will be considerably less than ¼ in. thick when smoothed and worked down. If it is only ⅛ in. thick, then it will hardly be too thin, though there is no object in making it so slight. Whatever the thickness, the groove should be a trifle wider, so that the shutter

will move easily and freely in it, though not too loosely. As it may, from lack of tools or other reasons, not be convenient to make the grooves just the right width, as will be seen later on, the shutters themselves may be adapted to fit in slightly narrower grooves. At present we may assume that these can be made exactly of the required width. I must now refer to Fig. 4, which represents the inside of right-hand end of the ease. These ends, by the way, may as well be of ¾ in. stuff, for if thinner there may be a difficulty in making the grooves deep enough to give sufficient bearing for the shutter. Along the front edge cut a rabbet the width of the thickness of the shutter, and about half the thickness of the end in depth. The rabbet, it will be seen, merges itself into a groove between the two tops, and, in order that the shutter may work freely, the groove follows a circular line instead of turning sharply. The length of the groove may be determined by actual measurement, but it will be as well in the first place to make it excessive, and stop up the excess after the shutter has been fitted. The bottom and sides of the groove should be cut as cleanly as possible, in order that no obstacle may be presented to the free action of the shutter, which, when all is fitted up, should run as smoothly and easily as a well-made drawer. To ensure this, careful construction and adjustment are necessary. Both ends, of course, are made exactly alike.

The shutter itself is composed of narrow strips of wood, in length just sufficient to reach from the bottom of one groove to the same in the other. It may, therefore, be well to suggest that the case should be fitted together, if only temporarily, before the shutter is made, in order that no unnecessary waste of time may be caused by having to alter this. The width of each piece must be so that it will pass the rounded corners without jamming in them ; and to avoid any risk of this, the groove at the corners may be slightly widened if necessary. As will be seen, however, the necessity for this must be determined by the width of the slips of wood forming the shutter. As some idea, it may be said that these pieces should not be more than ¾ in. wide, but they may be as much narrower as desired. The narrower they are naturally the more work there will be in connection with them. As a happy medium, let it be supposed that ½ in. is the width of each piece. So far as actual utility goes, each strip may be perfectly plain and flat, with square edges ; but the appearance of a shutter formed of such pieces would not be so nice as could be desired. The joints between each will be unpleasantly conspicuous, so that to adopt some plan by which we may "break the joint" will be an improvement. The easiest way will be to round off each edge, so that the section of the pieces will be as shown in Fig. 5. Two of these being placed close together, the actual line of the joint is thus hidden more or less completely, so that a shutter formed of several pieces shaped thus presents the appearance of being composed of a series of wide beads. Of course, instead of being rounded, the edges may be simply bevelled, as in Fig. 6 ; or the pieces may be of any section desired. Thus the shutter may be made to resemble a series of small, half-round beads, as in Fig. 7, where the joints may be noticed as indicated between the various pieces. The shutter might be made up of a number of pieces, each the size of the beadings shown, but to do so would entail an unnecessary amount of work, and no advantage would be gained, unless it may be considered that the trifling saving in the waste space between the outer and inner top, which may be effected by the rounded corners having a sharper curve, is a sufficient one. Appearance and convenience will be equally consulted by having each piece with several beads on it. Those shown in the illustration may be taken as being of reasonable size, but there is no reason why they should be strictly adhered to. Now a few words on the easiest and quickest way of forming such a shutter, and the remarks apply more or less closely to any section that may be preferred. The case being together, cut a board of the required thickness and of any convenient width : it is understood, I presume, that the grain of the wood is to be across the front of the nest, and of such a length that it just fits within the rabbet. See that the edges are truly squared, and proceed to work beads across from one edge to the other, using the "scratch" for the purpose. Those who are acquainted with this useful tool will hardly need to be told that after having run as many beads as the cutter will admit of, say, two or three, it is only necessary to remove the iron further in the stock to cut beads over the whole surface of the wood. Those to whom the tool is an unfamiliar one may be referred, with advantage, to the article entitled "The Scratch or Beading Router," in page 101 (No. 7), Vol. I., of WORK, where they will find all needful explanation how to make and how to use this useful appliance. After the beads have all been worked, pieces of appropriate width can easily be cut off with a fine saw without any appreciable detriment to the beads between which it cuts. If no fine saw is available, then leave a slight space when setting the iron between each two or three beads, so that the saw kerf, by removing this excess, will allow each piece to be fitted closely together. If preferred, the pieces may be cut before the beadings are formed, but this will probably be found more troublesome and tedious than the way suggested.

Another way yet may be more convenient, though, for reasons which need not be stated, it may not be so easy for those who have had little or no experience in cabinet-making. In reference to the width of the wood, which it was said should be cut to fit in the rabbets, it may be requisite to mention that if these pieces are of great width comparatively—say, more than five or six inches—they will not be easily manageable with the scratch. Now, instead of having three or four of such pieces, suppose that we have a piece much longer, and perhaps only three or four inches wide ; let the beads be run on to it for its entire length, and then cut pieces from it which will just fit in the rabbets, and we get a similar result to that already alluded to. So far as workmanlike proceeding is concerned, there is little or nothing to choose between this and the first method. It must just depend on the ideas of the workman, and the material available, which one he selects. It will easily be inferred, from what has been said, that other beadings or arrangements than those named may be chosen—such as those illustrated in Figs. 8, 9, and 10, which are given not by any means as implying that no others are available, but as suggestions which may be useful. The extent to which the mouldings of each slip may be varied is practically unlimited, and the worker can hardly go wrong with them if he is careful to have the joint sunk between two members, and not on a flat or projecting surface. The pieces being prepared, the next thing will be to fasten them together. Were this to be done by gluing the edges to each other, the door would be rigid, and for the present purpose useless. They must, therefore, be glued on to a flexible backing of canvas, calico, or some similar suitable material. Perhaps nothing is better than the ordinary "Hessian" canvas used by upholsterers, but those who have not got any need not take much trouble to procure it if something else is handier. Glue alone may be used as the adhesive medium, but a mixture of it and good strong flour paste may be regarded as preferable. The canvas may cover the whole of the back of the shutter, though it will be better to leave the portion which fits in the groove bare, or it may be in strips from top to bottom. All that is needed is that the pieces should be, as it were, hinged to each other. However close together they are—and the closer the better—they will not prevent the shutter bending in the required direction—viz., backwards—when it is turning the corners in the waste space. If, as is very possible, some glue has got between the pieces, be careful to remove it before it has set and firmly stuck them together. There will be no difficulty in doing this by bending the shutter backwards at each joint, and if this is done the additional advantage of rendering the shutter more flexible than it otherwise would be will be gained.

It may reasonably be supposed that a lock is to be fastened to the shutter ; and, so far, no provision has been made for doing so, for the thin stuff is not sufficient hold for one. In addition to the narrow slips, therefore, a larger one, both in width and thickness, sufficient, in fact, in both respects for a lock to be let into it, must be placed for the bottom one of the shutter. As this piece will only work up and down in the rabbet or straight part of the groove, and will not have to be worked round the corners, it may be of any reasonable width, and, preferably, it should be plain instead of beaded. Some may wonder how a piece of the thickness proposed can work in the groove. I cannot tell them how to perform an impossibility ; but this need not be attempted, as it is only necessary to reduce the thickness of the ends of this bottom piece sufficiently for them to fit within the grooves. For various reasons it will be better to have the extra thickness at the back of the door—*i.e.*, the front of this piece should be flush with the remainder of the front of the shutter. This, of course, can easily be managed by removing whatever wood may be necessary from the back only. I suppose it is not necessary to do more than hint that the lock may as well be got, or at any rate its size be decided on, before this bottom piece can accurately be determined. It will certainly be better to adapt the size of the wood to that of the lock than the reverse.

After the glue is dry, a trial of the shutter may be made, in order to see if it fits and runs well. The top strip should be high enough to enter the rounded groove while the bottom one is in its normal position, so that when all is finished the front will be quite closed. If care has been taken, there should be no difficulty in working the shutter backwards, or, as may perhaps rather be said, upwards, so that it runs within the groove easily and without catching anywhere. When it has been opened till the bottom of the lowest slip is on a level with, or a little below, the inner top, the remainder of the groove, if any, may be filled up by gluing a piece of wood in it, to act as a stop ; for, of course, the shutter will never have to be pushed further than the position named. Now, should the wood of the shutter be too thick to fit easily

within the grooves, just bevel it off till it is sufficiently thin to do. If much has to be removed, do so from the back; but if only a little, it may be done from either back or front. Possibly a little rubbing down with glass-paper may be sufficient.

Up till now the spaces which the shutter slides in in front can hardly be called grooves, as they are merely rabbets, and the door hangs in them curtainwise, so that it can be lifted forwards, instead of merely sliding up and down. To make grooves of them, or rather, to enclose the sides of the shutter, a couple of knobs fastened to the bottom piece will be found a convenience.

We may now proceed to apply the principles so fully explained of shutter construction to a nest of pigeon-holes such as we started with, so that when finished it will be like Fig. 11. As readers will remember, it was oblong in shape, considerably so, there having been three rows of nine holes each. Without saying that there might not be a fall-down front, like that described for a smaller nest, such a construction would, to say the least, be inconvenient, and therefore unusual. Instead am wrong in this supposition, I shall be happy to explain anything which may not be quite clear in "Shop" to any inquirer who may meet with a difficulty which he cannot surmount. At the same time, I must ask him to remember that "Shop" is rather overcrowded than otherwise, and not to write for a solution of any difficulty which a little consideration on his part, or experiment, either in working or drawing, might have removed. If he will read the directions for making and fitting a fall-down front, and then imagine that a nest with a double door,

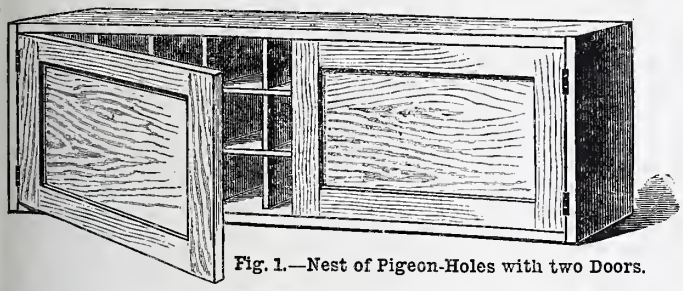

Fig. 1.—Nest of Pigeon-Holes with two Doors.

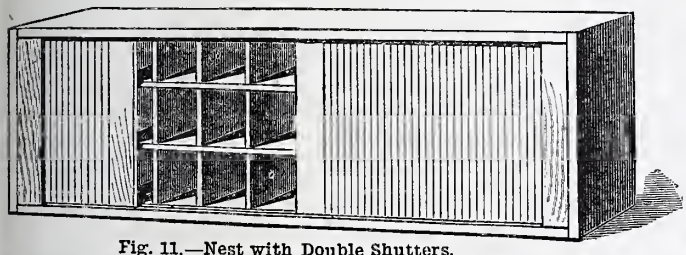

Fig. 11.—Nest with Double Shutters.

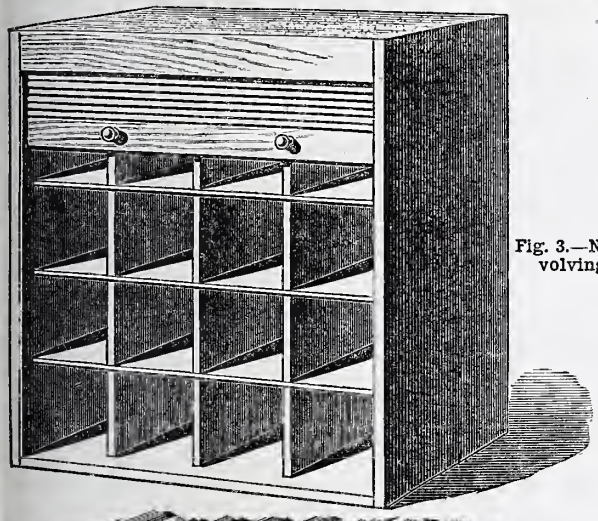

Fig. 7.—Three Strips all Beaded.

Fig. 5.—Shutter Strip with Round Edge.

Fig. 6.—Shutter Strip with Bevelled Edge.

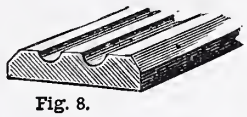

Fig. 8.

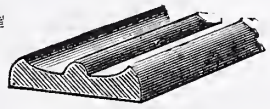

Fig. 9.

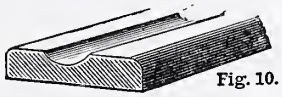

Fig. 10.

Figs. 8, 9, 10.—Alternative Forms for Strips.

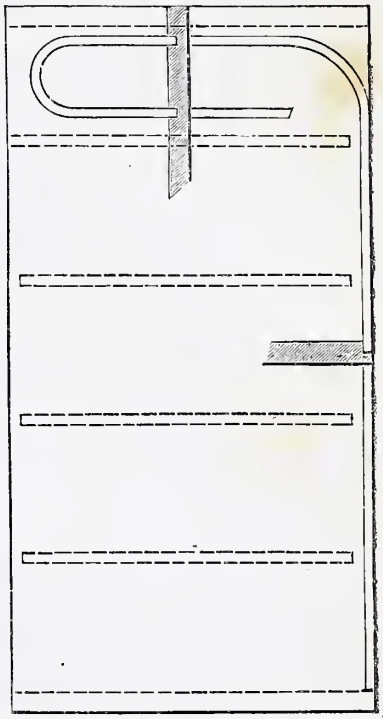

Fig. 4.—End of Nest showing Groove and Rebate on Front Edge. Dotted Lines show Position of Shelves.

Fig. 3.—Nest with Revolving Shutter.

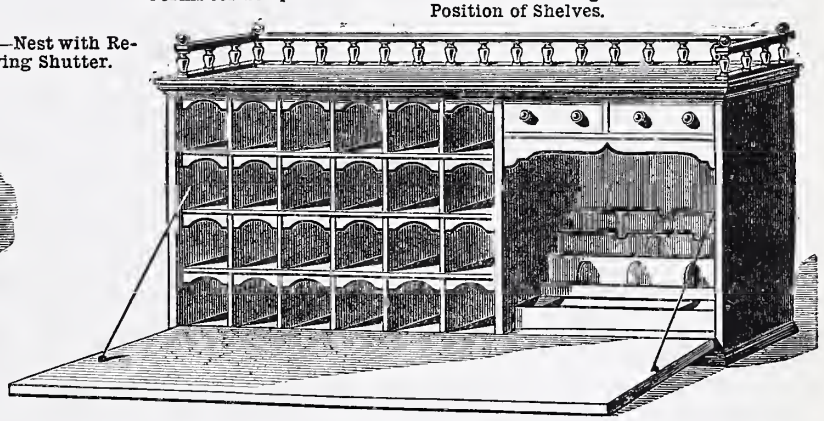

Fig. 2.—Nest with Fall-down Front for writing on.

glue thin slips of wood on the front edges. Provided these slips overlap the sides of the shutter, their width is not important, but it may as well correspond approximately with the thickness of the ends. The shutter being in its place before these pieces are glued on, is now securely fastened, so that it can only move up or down. To bring up the edge of the bottom flush with the ends, a similar piece must now be glued on to it. The same must be done at the top, but the piece there must be of a suitable width; and it may no doubt occur to many that a piece of moulding may be planted on it and carried round the ends. In order to raise and lower the of one shutter sliding up and down, it will be better to make two, opening sideways from the centre. In this case no double top will be wanted, as the shutters will turn into the ends, each of which, therefore, must be made double. The rabbets must be on the edges of the top and bottom, and the grooves will naturally be in the same pieces. Is it necessary to say anything more about this construction? Surely not, for those who have not got a sufficient amount of common sense to see what is required, if they have read all that has been said, could hardly undertake to make a nest with double doors even with full directions. Still, if I sliding sideways, is merely a double-ended one with what was the top for one end, I do not think any mistake can be made.

To prevent the doors when locked from being pushed on one side, and so allowing of access to any of the holes being obtained, and to prevent either door being drawn too far, a stop should be placed at the centre in the rabbeted groove. This can easily be managed by cutting a small corner out of the doors, just where they come in contact with the stop.

With a few general remarks this article must be brought to a close, for the principles of folding-shutter making have been

sufficiently explained to enable almost anyone to do what is requisite, provided he has the manual skill necessary. Instead of the shutters when opened being folded entirely by the ends and top, they may simply pass through the space and in behind. In this case naturally two backs will have to be made, so that the labour involved in making the nest is increased. When the height or length of the nest is great in proportion to the depth from back to front, it will be plain that this form of construction is better than the former, and may be the only one possible.

The amateur will rarely have occasion to make a very large shutter-front, but with the professional cabinet-maker the case may be different. It may, therefore, be well to suggest for his benefit that when the shutters are heavy and open sideways it is sometimes advisable for them to run on rollers. The fitting in of these he will, however, require no special directions about; but should anyone want to know, it is, as I have said, only necessary to ask for a reply in "Shop." Anyone doing so will please note that the dimensions of the case and thickness of the wood used *must* be given.

## MEANS, MODES, AND METHODS.

### A Novel Use for Clothes Pegs.

The ordinary wooden clothes pegs, which are sold at one penny per dozen, of all hardware merchants, can be turned to a variety of uses by the worker in wood.

The peg, if cut off above the point in which it divides in two, forms a very respectable substitute for a turned pillar in the manufacture of "antique" furniture, especially if it receives a few thread-cuts in the lathe, but this is not at all necessary. I have used dozens of them without any further addition than a rub of sand-paper,

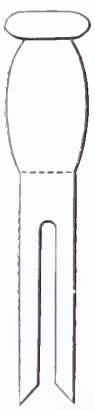

Fig. 1.—Turned Wooden Clothes Peg.

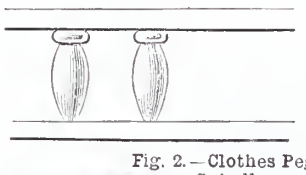

Fig. 2.—Clothes Peg as Spindle.

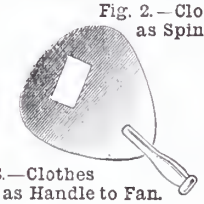

Fig. 3.—Clothes Peg as Handle to Fan.

and my friends have been greatly surprised when told of their origin.

Another use to which they can be effectively put is in the manufacture of handles for the numerous class of substantial "fans," such as have spaces for portraits cut in their surfaces.

All that is necessary is to cut off the two sloping tips of the peg and insert the leaf of the fan between the two sides, securing it in position with either a nail, screw, or glue, and painting or gilding it, according to taste.

A form of the wooden clothes peg as made by the turner is shown in Fig. 1; in Fig. 2 an example is given of its use as a spindle; and in Fig. 3, how it may be used as the handle of a fan. Without doubt the suggestions here given will prove useful, and many will be led to adopt them.

## OUR GUIDE TO GOOD THINGS.

*** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

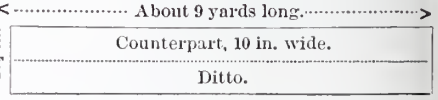
### 40.—Engel's New Transfer Graining Sheets.

There are many amateur workmen—yes, and many professional workmen, too—who can use the brush and contents of the paint-pot well enough as far as plain work goes, but who would be utterly nonplussed if they attempted to take a turn with the graining comb and cloth, or sought to do anything in imitation of natural wood or marble. The work of the amateur is confined to painting in unbroken stretches of various colours, or to staining and varnishing; and the painter who does mere ordinary work is obliged, through lack of natural ability or mechanical aid, to leave the imitation of woods and marbles to men who make this kind of work their speciality. But, thanks to Mr. George Engel, 18, Castle Street, Falcon Square, London, E.C., who manufactures and supplies the "New Transfer Graining Sheets," and who, I presume, is the patentee, natural ability for graining and marbling is put into the shade altogether, and mechanical aid is brought within the reach of anyone and everyone who may care to avail themselves of it. Having seen the sheets and the results produced, I am longing to have a turn at the work, but the pleasure must be deferred until leisure permits, and when that will be, "goodness only knows," as the ladies mildly put it, for with me, as time turns on, toil seems to increase instead of lessen, and I don't care to follow the fashion and go on strike—just yet awhile, at all events, although there is no knowing what the force of example may bring about in the future. However, I can readily endorse Mr. Engel's statement that these sheets are a boon to decorators and painters, that graining by hand is—in many cases—completely surpassed, and that the working is remarkable for its simplicity, rapid, and economical, and the results obtained as effective, certainly, as many of the best attempts at imitation that we see, and often as telling as natural wood or marble.

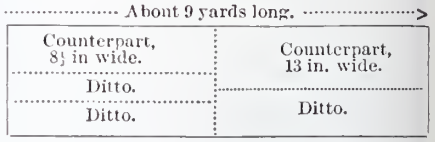
That these assertions are such as will hold water will fully appear when it is explained that, after the fashion of the coloured transfers which are sold for the amusement of children, these sheets are so prepared that the grains of oak, walnut, maple, ash, mahogany, rosewood, etc., as well as every kind of marble grain, can be transferred on to surfaces painted in the ordinary way by simply wetting the back of the paper. Everybody knows—or I presume that it is so—that when a surface is to be grained it is first painted over with the proper colour that forms, so to speak, the groundwork of the graining. This being done, the following are the instructions for graining with the transfer paper:—"Cut the transfer paper a little larger than the size required, place face downwards on a dry, clean table, and wet the back well and evenly with a *half wet* sponge, taking care not to let the water stand on the back of the paper. Let the paper soak for another three or four minutes until the grain print begins to get glossy. Wet the surface to be grained with a sponge, distribute the water well by rubbing over with a stiff hair brush, that the surface becomes *evenly damped, but not too wet*, place the transfer paper face downwards on the moistened surface without creases, rub the back well with the same brush, take off the paper, and go over the grained surface with a softener *at once, while wet*. The paper will make four or five *good* impressions while wet." The operator is advised to use stale beer instead of water for wetting the paper, or a mixture of half stale beer and half size water. After the grain is perfectly dry, it should be smoothed over with glass-paper, and boiled linseed oil applied by means of a rag. When dry, the graining and the surface to which it has been applied should be varnished in the usual way.

"The work is simple enough, anyhow," many a reader of Work will doubtless say. Yes, that is so; and it is as rapid as it is simple, for, after a little practice, inexperienced hands—that is to say, hands who cannot grain or marble in the usual way—can use the sheets, and by their instrumentality do the work twenty times quicker than any artist can grain by hand. As to its effectiveness, it need only be stated that the manufacturer says the designs are impressed on the paper from natural woods and marbles, and that the work thus done is scarcely distinguishable from the wood or marble it represents.

As to its cheapness, and therefore economy in the use of the sheets, it may be said that the cost of material used in graining a square yard may be estimated at being about a penny, and that the application of the paper to such a surface takes only five minutes. The manufacturer says that "to grain and varnish a yard takes only five minutes," but as this involves a duplex operation, I am not prepared to go with him as far as this. As to the form in which it is given to the public, it should be said that the "Patent Transfer" is sold in rolls of about 9 yards long in two widths —20½ inches and 26 inches. The 20½ inch wide rolls are made in one continuous grain of 20½ inches, and also in two counterparts, each of 10 inches wide, as shown in the accompanying diagram:—



The 26 inch rolls are made in one continuous grain of 26 inches, and also in two counterparts, each 13 inches wide, or in three counterparts of 8½ inches wide, as shown in the diagram given herewith:—



From these sketches it will be apparent that the paper can be cut to the required sizes for any kind of work, with little or no waste. The varieties of wood grains usually supplied are—*Oak*, light, medium, and antique; *Walnut*, American and soot; *Ash*, in two varieties; *Maple*, bird's-eye, silver, grey, and yellow; *Cherrywood*, *Rosewood*, and *Mahogany*. Marble grains are made in all varieties in rolls of the same length and width as those of imitations of woods. There are over a hundred designs from which a selection may be made, and the maker will send a sample roll 20½ inches wide for 2s. 6d., post free. Otherwise, the 20½ inch rolls are supplied at 2s. per roll, net, and 26 inch rolls at 2s. 6d., postage per roll in each case being 3d. extra. For orders of at least fifty rolls discount is allowed to the trade.

I have dwelt at length on the Patent Transfer Papers, because I regard them as being among the best things to which I have been privileged to call attention for some time, for any amateur who is so inclined may grain a chest of drawers or the woodwork in his house with the utmost ease; and the professional painter in any country town or village who has not ventured hitherto to attempt the higher branches of his art, may do so now without any fear of failure or of causing disappointment through want of success in any imitation which he has undertaken to effect, whether in wood or marble. I mentioned them to a jobbing carpenter the other day, who does a good deal in house-repairing, and he jumped at the notion like a trout at an attractive looking fly on a dull day. It showed him, in fact, how he might venture on painting of a more ambitious character than that which he has hitherto attempted.

The Editor.

# SHOP:

## A Corner for Those who Want to Talk It.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—Letters from Correspondents.

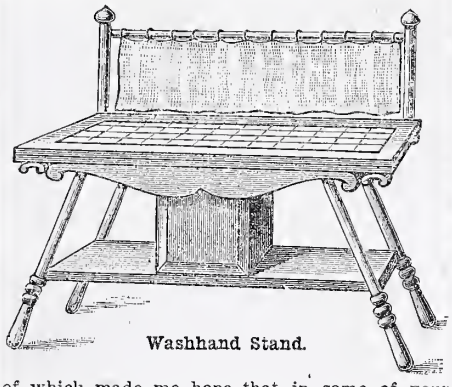
**Drawing One's own Specification for Patent Office.**—Another Inventor writes:—"I have been very much pleased in reading the article by Inventor, entitled, 'Some Words to Would-be Patentees,' in No. 116 of Work; and having obtained a protection for an idea of mine (thanks to Work), I thought that perhaps a few lines from me would be of help and encouragement to others who, like myself, wish to protect an invention, but do not care to pay the sums generally charged by patent agents. So having worked out my idea, I was about to go and see an agent, in whose hands I intended to place the job; but on calling on a friend who had done a little business through the Patent Office, he advised me not to, but to get the forms and do it myself. So after getting home, I referred to my Index of Work, Vol. I., and read the articles by C. C. C. and others. After getting the forms from the post-office, I started to fill them in and draw out the specification, which I found easy after the advice given in Work, and then posted them off to the Patent Office. The next few days brought me letters from firms at London, Paris, Brussels, and Berlin, all offering to render me assistance on very reasonable terms; and one kind friend wrote to inform me that my specification was informal, and not so full as it ought to be, and that I should have it returned in due course from the Patent Office: that if I would place the matter in his hands, he would make what alteration was necessary for 5s. 6d. It is, of course, unnecessary to state that I took no notice of these letters, but waited patiently for my specifications to be returned—which really did take place, as prophesied by my friend. In the course of a few weeks I received my specifications back for amendment, which amendment consisted of the alteration of three words, and which alteration my friend offered to do for 5s. 6d.—very reasonable indeed! After altering, I again sent them up to the Patent Office, and in a few weeks received a form saying my application was granted. I really think, with Inventor, that the officials at the Patent Office do all in their power to assist inventors. But I think I am mainly indebted to the advice and help given in Work, which so materially assisted me in filling up form and specification; and as I have Work from its first number to this week's—the two first volumes bound and indexed—I shall prize it more so because of the help it has rendered me on this particular occasion."

**Rate of Circular Saws.**—Chopstick writes:—"I cannot resist the temptation to reply to Woodworker's letter on the above subject (see Work, No. 116, page 187), as the arguments he makes use of are not only very misleading, but altogether absurd. In the first place, can he find any joiner who will cut a 3 in. plank with the rip saw? if he can, I think they must be fond of work in his neighbourhood; and secondly, I will defy any man to cut wood of that thickness at the rate of speed he mentions for any length of time. And now a word in favour of the machine which he condemns so strongly. I have, on a home-made machine, cut 3 in. deal, and the man who turned the wheel preferred doing it that way to cutting it with a rip saw, and it was certainly cut in half the time and in a better manner. For cutting thinner stuff, and also for rabeting, grooving, etc., the advantages are far greater; and I will even go so far as to declare that no shop should be without one of these useful tools, as they will repay their cost double and treble. If the cost is too much for an iron one, a wooden one does equally as well, only the bearings should be well fitted, and the fly-wheel should be heavy. Then, with a labourer to turn, you will soon find out the fallacy of Woodworker's arguments."

**Fillers in French Polishing.**—W. D. (*Newington Butts*) writes:—"I know of no better filler than what is given by David Denning (see page 166, Vol. III.). All new work will sweat in time, as the oil used in polishing will find its way through the film of lac. I use Russian tallow mixed with plaster of Paris, with rose-pink for walnut and mahogany. A good filler-in for oak and ash is water and methylated spirits (used as water), and plaster of Paris, coloured with rose-pink, for brown oak, and yellow ochre for light oak or ash. Pumice powder can only be used with advantage by experienced French polishers. A preliminary rub with polish before filling-in will not only keep the grain smooth, but stop the sweating to a great extent, as there would be a foundation of polish. 'Filling-in' is the term used by French polishers."

**Holes in Girder Webs.**—A. B. (*Salford*) writes:—"Mr. J. W. Harland, in an article on 'Constructive Strength in Metal Work,' in Work of 30th May last, speaking of cast-iron girders, remarks that 'it is very bad construction to drill holes in the web itself,' and proceeds to give his reasons for this statement. He also says that 'the nearer the hole to either flange the less dangerous it becomes.' I think it necessary to point out to your readers that *Mr. Harland's view of this question is entirely opposed to the teaching of all the leading engineering lecturers of the day, as well as to practical experience.* The one place, above all others, where it is possible to drill a hole in a girder with the least damage to the strength of the girder is in the neutral axis, or the line passing along the web where the compression of one flange gradually fades away, if I may use the expression, into the tension of the other flange. Any good work on mechanical engineering will explain this. At present I will refer your readers to Professor Perry's 'Practical Mechanics' (Cassell & Co.), where, in Chap. XI., they will find the statement that the neutral axis passes through the centre of gravity of the section of the beam; and what is more to the point, to Sir John Anderson's work on the 'Strength of Materials,' Chap. XII., where they will find the words: 'The neutral line is the part where holes for fixing other parts connected with the girder may be made with impunity.'"

**Washhand Stand.**—A. H. W. (*Newcastle-on-Tyne*) writes:—"I venture to send you a rough sketch of a washhand stand in the suite, the sight



Washhand Stand.

of which made me hope that in some of your numbers I should see a paper on simple artistic furniture. In my sketch I have not reproduced enough elegance, I know."

### II.—Questions Answered by Editor and Staff.

**Electric Belt.**—A. C. (*Burnley*).—Commencing at the left-hand end of your belt, as sketched, let the top dise be of copper, the next below it of zinc, the lower disc of copper, the lowest dise on the next row of zinc, the middle dise of copper, and the top one of zinc. This will form one battery of three pairs of elements in that section of the belt. Connect them in pairs, copper to zinc. Treat each section of the belt in the same manner. You will then have four batteries in one belt. You may adopt another arrangement, if you choose to do so, by having each alternate row of discs made of copper, and the other of zinc. I see no advantage, however, in your arrangement over that recommended to G. F. R. (*Woolwich*), p. 827, Vol. II. The current generated in your belt (if any) will be of low tension, owing to absence of outside discs. I should advise you to sew pieces of magnetised crinoline steel in the belt instead of the copper and zinc discs. Let the steel strips lie in the same direction as the whalebone, and cover them with flannel. A magnetic belt of this kind will do you as much good as an electric belt.—G. E. B.

**Magnet, etc.**—A. G. (*Sheffield*).—(1) The diameter of the magnet is not a point to cause much thought; it may be anything. I think I mentioned it in my article; if not, I have unconsciously omitted it: I meant to have stated ⅜ in. Get it that diameter, and you will be all right. (2) Where can the magnets, etc., be obtained? At the address given on the circular or any other electrical supply store. (3) I cannot give instructions here for making a transmitter like the one in the cut on the circular, for two reasons; the first being I do not know what kind of a transmitter the cut represents; the second being that it would require too much space—more than is available in this column. I have already given instructions in "Shop" for making a very reliable form of transmitter; and an article is in the Editor's hands, giving details of a switchboard and method of connecting up bells, etc. All the instruments can be joined up with one line wire. (4) About No. 28 wire will do for the line—about 1d. per yard.—W. D.

**Blocking Cards.**—Anxious.—There are several methods by which cards can be blocked with Dutch metal. You ask for a dry process. The most simple is the following: Get some common resin and pound it very fine; tie it up in a cotton rag, and dust it over the part where you want the metal to stick. Now, having heated your blocking press and stamp, take up a leaf of the metal and lay it over the stamp; place your card in the press, and block in the usual manner. It will be easier if you can take out the plate of the press readily upon which the stamp is fastened, and replace again. There are small presses for this class of work made and sold now by most makers. After the blocking has been done, the superfluous metal is dusted off with a piece of rag. Let your stamp be very hot.—G. C.

**Faulty Dynamo.**—T. S. (*Hull*).—You have not described the castings of the dynamo, so I am left to guess what it is. I suppose it to be of the Gramme type, but even now do not know its size, so can only guess this also. Readers asking advice respecting dynamos, must give full dimensions of the magnets and armature, and also describe the type of machine. I think you have enough wire on the fields and armature to give current equal to 30 c.-p., but not enough to send current through a lamp requiring 30 volts. Your lamp is a 30 volt 8 c.-p. lamp. If you connect the three lamps in one circuit in parallel, the resistance of the circuit will be reduced, and you will be able to light the three lamps where you have failed to light one. If you have room on the armature for a few more turns of wire, put them on, and balance this with about 200 yards more of wire on the fields. When amateurs find their machines going wrong, they should first write to the vendor of the machine or the maker of the castings.—G. E. B.

**Bicycle Building.**—J. S. (*Wimborne*).—A series of articles on Bicycle Building is running through the present volume (III.) of Work.

**Seal Gas Engine.**—Nemam.—The address of the maker of this engine is: J. Seal, 67, Carthew Road, Hammersmith, London, W.

**Incubator.**—Chick.—A description of an incubator appeared in "Shop," page 651, No. 41, Vol. I.; also an article on same in No. 89, Vol. II. On page 762, No. 99, Vol. II., you will find some remarks of mine on the subject; and on page 75, No. 109, Vol. III., some further remarks, with a description of a regulator. Get these four numbers from your bookseller, or the publishers will send them post free for five stamps. In the course of a week or two an article describing a "hot-air" incubator will be in the Editor's hands, and will doubtless appear in good time for you to prepare a machine for use next season. It is too late to think of commencing one for work this season.—Leghorn.

**Incubator.**—G. H. (*Hackney*).—See reply to Chick above.—Leghorn.

**Mending and Stopping Terra-Cotta.**—R. L. (*Ruabon*).—If R. L. has not tried shellac dissolved in spirit for mending, he should do so. For stopping cracks or faults, we presume that fresh, quick-setting plaster of Paris, with some of the terra-cotta pounded to dust to give the required colour, would suffice.—M. M.

**Duplex Telegraphing.**—R. B. (*Edinburgh*).—This subject must wait for an article. It would occupy too much space in "Shop."

**Purfling Gauge.**—H. McC. (*Kilmarnock*).—Refer to the advertisement columns in the last few numbers of Work, and you will find the address you require.—B.

**Xylonite.**—Tevot, A Fretworker, and others.—The address of the Xylonite Company is: The British Xylonite Company, Limited, 124, High Street, Homerton, E.

**Carpenters' Society.**—J. R. (*Kilmallock*).—We know of no branch to recommend.

**Toy Cylinder.**—Cylinder.—This is a question that can only be answered by describing the entire mechanism of a steam engine, for which there is not space in "Shop." If you will read the article now appearing on a Quarter Horse-Power Engine, you will obtain a complete answer to your query.—J.

**Drills.**—W. G. (*No Address*).—These drills will do very well if tempered a little harder. They go through brass, but I find they lose their edges on iron. But I do not see any advantage in using common umbrella ribs, when you can buy steel wire suitable for the purpose, wire that will temper better.—J.

**Galvanising, Enamelling, etc.**—Holly Reader.—It is not within the province of amateurs to enamel iron plates. It requires special and expensive plant and material.—R. A.

**Green Stain for Holly.**—P. O. C. (*Cork*).—This is usually made by dissolving verdigris in hot vinegar till the required shade is procured, or the crystals of verdigris in hot water. But the aniline dyes, as sold in packets or tubes for a few pence at most druggists and drysaltery stores, will be found to meet all requirements, if only a small quantity—say a quart—is needed, especially if a little vinegar is added as directed. It will be well to bear in mind that the hotter these stains are applied, the more deeply will they strike in.—Lifeboat.

**Accordion Reeds.**—H. C. (*Whetstone*).—As accordion reeds cannot be sharpened more than quarter tone, a new reed should certainly be fitted to the instrument. The method of tuning these is as follows:—To sharpen, file the reed thinner at the free or vibrating point; to flatten, thin it near the fixed end.—G

**Enamelled Paper Letters.**—A. J. R. (*Norwich*).—Beit's patent enamelled adhesive waterproof advertising paper letters and figures, in all colours and sizes, can be had from makers, 17, Arthur Street, New Oxford Street, W.C.—H. L. B.

**Case Hardening.**—C. T. & Co. (*London, E.C.*).—No process of "hardening" will make iron or steel rust proof; highly polishing it has a tendency to prevent rusting. If the goods are only required to be rust proof during transit, heat them a dull-red heat, and let them cool in the air, when a thin film of the insoluble black oxide is formed. If the goods are now brushed over with oil, they would travel ten times round the world without rusting. Galvanising iron or steel goods is about the best protection, and is largely being adopted for all exposed ironwork. I have often wondered why exposed ironwork is not more enamelled, as all kinds of shades and tints could be used, even transparent enamel. Such would last for ever, never want painting, and every shower would wash it clean.—J. H.

**Bookshelf for Bedroom.**—J. C. (*Halifax*).—A convenient form of bookshelf for the bedroom is the one herewith drawn. Its advantages are that it can be removed in an instant, and replaced elsewhere without leaving or causing any disfiguration to the wall. It is much to be preferred, for the use required of it, to a shelf supported by brackets; and, as is apparent, requires less labour in its construction. Again, the side strings form a kind of preventive against the books slipping off endways. A very small nail, driven into the wall at each end so as to allow its head to press against the end edge of the shelf, will retain it in its proper position; for without such an aid it would slip to the right or to the left, according to which side happened at the time to bear the most weight. You can see from Fig. 2 that it is merely a board supported by strings whose knots are underneath it, slung round large-headed nails.—J. S.

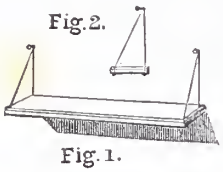


Fig. 1.

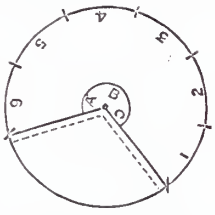
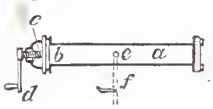
Bookshelf for Bedroom. Fig. 1.—Bookshelf in Perspective. Fig. 2.—End of Shelf in Elevation.

**Paraffin Bottles.**—BLACKSMITH.—You do not state what size bottle you want to make, so I here give you the sizes to cut the bodies of 1 qt., 2 qt., 4 qt., and 8 qt. I expect these will be as many as you will require: 1 qt., 13½ in. by 4⅜ in.; 2 qt., 19½ in. by 6⅜ in.; 4 qt., two pieces 11 in. by 7½ in.; 8 qt., two pieces 13¾ in. by 9¼ in. To cut out the tops, set your compasses at a radius of three-fourths of the diameter of the body, measuring from out to out of edge, and draw a circle; then set the compasses to *half* the diameter of the body measured as before. Set off six parts round the circle previously described, and draw lines to the centre; see sketch, which will explain it clearly. The dotted line shows allowance for seam about ½ in. each side. This is a rough method of getting at the pattern for the tops, but it gives fairly correct results.—R. A.



Pattern of Bottle Top—A B C, Small Circle for Neck of Bottle.

**Bending Tonkin Bamboos.**—J. W. P. (*Leeds*).—Probably our correspondent has no very complete apparatus for bending his bamboos, or we see no reason why he should have found difficulties with his tonkins. They bend readily from such a steamer as that shown in the annexed diagram. In this *a* is the receptacle for bamboo, etc.; *b* is its lid, which has an elastic washer, and is opened and closed by the screw *c*, worked by the winch *d*; *e* is a supply pipe from an engine boiler, which has a stop-cock at *f*. The strips of wood are placed in the receptacle, the lid screwed close, and the steam turned on. Ten minutes more or less may be required, according to its rigidity, to soften the wood sufficiently; the tonkins will need full time or perhaps super-heated steam. When the wood is softened, the steam is turned off; one man works the winch, and opens the lid just so far as to allow a second man to take out a strip, which he bends and wedges in place *instantly*, and so on till the whole are bent. But quickness of action is essential; a minute's delay may chill the wood and cause a breakage. Steam is mostly used to bend, dry heat to straighten.—S. W.



Steamer for Bamboo.

**Opaque Objects.**—F. B. (*Taunton*).—F. B. asks for a "liquid to make a dull black background for mounting microscope objects." The following will, I am sure, answer all F. B.'s requirements: Brunswick black mixed with a small quantity of a solution of indiarubber or mineral naphtha. This latter will prevent cracking. Place the slide on the turn-table, and make a central disc, having first warmed the glass. Give it two or three applications, if need be. Let the last coat be dry before another is applied. By repeating the operation on the edge, form the cell to the desired depth. Some mounters cement a disc of cardboard or black paper on the underside of the slide, in addition to the black cement, but if carefully done, I do not think there will be any need.—O. B.

**Ladies' Work-Table: Joints for Legs.**—J. J. A. (*Wandsworth Common*).—Connect columns to the middle and bottom boards of my Ladies' Work-Table and Escritoire (No. 56, Vol. II.) after some such manner as I hereafter illustrate. By preference, adopt my suggestions concerning middle board in Fig. 17, page 53, in the same number. You can then dowel it by means of three or more pins to the column blocks. For sufficient details dealing with dowelling, read my article, "Combined Music-Stand," etc. (No. 35, Vol. I.). An alternative

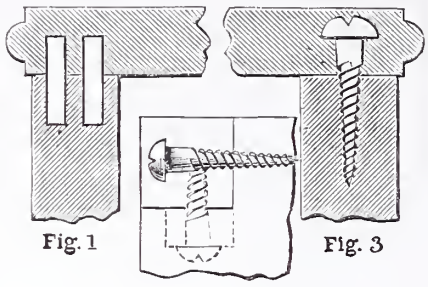


Fig. 1 Fig. 3

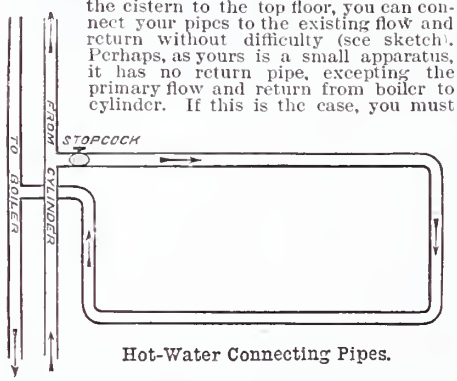
Fig. 2

Screws for Leg Joints.

method will be to secure both by utilising strong stout screws, as in section (Fig. 3). If, however, you desire to build the article exactly as it is shown in my drawings as complete, you must join the middle board in the same way that I am about to describe the junction of the bottom board with the pillars. You may have two stout dowel pins to one inner side of the column block, and have a stout screw passing through the remaining inner side; or drive a screw in as in Fig. 2, and insert a separate and rather small square of wood against the block, touching the underside of the bottom board, and there screw and glue it to all adjacent parts. Afterwards fill up all screw holes.—J. S.

**Hot-Water Service.**—RELAW.—If you remove the cistern to the top floor, you can connect your pipes to the existing flow and return without difficulty (see sketch). Perhaps, as yours is a small apparatus, it has no return pipe, excepting the primary flow and return from boiler to cylinder. If this is the case, you must



Hot-Water Connecting Pipes.

carry a return pipe from your coil into the side of the cylinder near the bottom, or you may carry it into the primary return from cylinder to boiler.—T. W.

**Lasts.**—S. T. (*No Address*).—(1) Evidently the last is out of range for the height of heel you wish to make. If it is not much, it can be counteracted by feathering the insole, and sewing close and full, as explained in answer to A. B. (see page 796, No. 101, Vol. II., of WORK); but the last being very bad, it must be remedied by altering its construction. The plain lines describing the lasts in Figs. 1, 2, and 3, are all the same; and it will be seen by Fig. 1 that it is somewhat dead, or flat in the waist. Well, by building a high heel, one lift above the other, without reducing them at the breast, will throw the heel out of range, as shown at A, B, and C (Fig. 1); and if they are reduced at the breast to give a better range, when the boot is worn, and the pressure of the foot put on D, it will press it down to the ground line, and again throw it out of range. To fit the last to prevent this there are two ways, and if the last fits anyone, and has still to have low heels made on them, it will be best to alter them in a way that they may quickly be brought back to their original shape with little trouble. For this, first take the measure of the last round the joint at A B (Fig. 2), and then peg a piece of leather—that has been wetted—on the bottom of the last from C to D and right across; skive the leather down, as shown by the dotted line at B, tapering to nothing at C and D, but making it more gradual from B to C than from B to D. Then rasp the wood away, as shown by the dotted line at A E, until it measures the same as when it was first measured. Then peg another piece of leather on the heel. Let it be quite thick at F, and tapered to nil at G; a little can be taken off the wood at H the other way, and if they are to be used for high heels only, it will be the best. Rasp a piece off the bottom at the toe, from A to B (Fig. 3), as shown by the dotted line, and also from C to D, taking it away most at E, and then this deficiency can be made up at F and G with leather. The plans of the two bottoms are given in Fig. 4, to contrast the pitches of the same heel on the two different lasts. (2) Yes; the insole of pegged boots should be made broad, and thinned down at the edge, but it should be left its original substance where the pegs are going. To bring the range right for pegged work (as it cannot be feathered and sewn full to set it right), it must have a wedge-lift pegged to the insole, before lasting (as A, Fig. 5). This is done to have the same effect as produced by altering the last, only that it is left in the boot where it is not seen. It need not be a whole lift—a split lift will do—but it must be thick at A. But I would advise you to alter the last as much for one as the other. (3) A split lift is put in, in building the heel of sewn boots, to level the seat (to receive the whole lifts), which would otherwise be round in the centre, and necessitate cutting the centre away, and making a part of the boot weak that should be most solid. (4) If you are making light pegged work, the "slip" sole

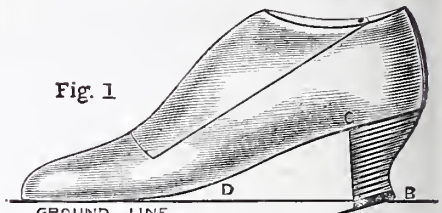


Fig. 1

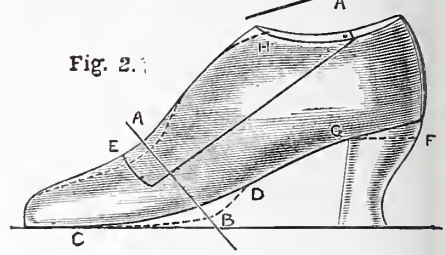

Fig. 2.

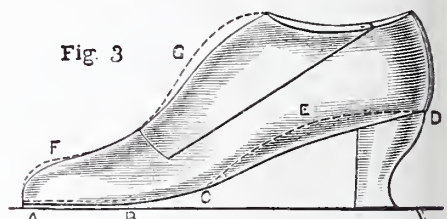

Fig. 3

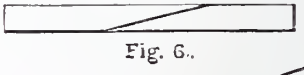

Fig. 6.

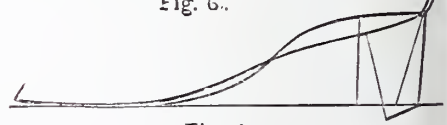

Fig. 4.

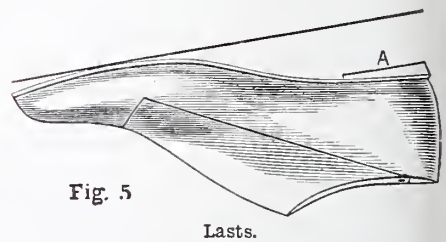

Fig. 5

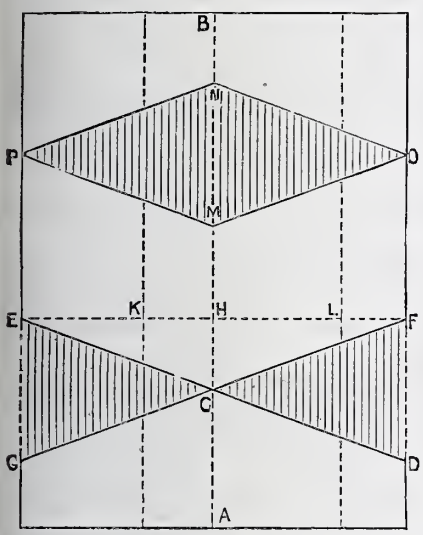
Lasts.

(or middle sole) need not be a sole at all, but simply a runner. Measure the forepart from joint to joint, and cut a piece of leather the length, and about 1½ in. wide. Split this down the centre as you would a split lift, letting the cut be only ½ in. wide (as Fig. 6); this will give ¼ in. each side of solid stuff to peg through. Skive it a little wider and thinner at the toe, that you may get it round smoother. It should be a firm piece of leather (first cut is best); it can be any substance you like. Hammer it, peg it on, cut the pegs off, and skive it down to what you like towards the centre; fill the bottom up in the ordinary way. By this means you have it as flat or round as you choose. No matter how broad the bottoms are to be, the pegs must be sufficiently far enough from the edge to let them go well through the insole—quite ⅛ in. from the edge of it. You will find it best to slant the edge with an ordinary knife, but be very careful not to cut the upper. Hold the piece you are cutting away in the left hand, and keep twisting it between the thumb and finger, and only use the extreme point of the knife, guided by the second finger of the right hand. The forepart iron will do, as for sewn boots. (5) To

hole the soles of pumps, use a sewing awl—the one you are going to sew with, or one a shade larger will do. (6) A welt iron is used for the welt side of the edge, while a forepart iron is used for the sole side; or in other words, a double iron is a welt and forepart iron combined, but a more superior piece of kit, and much harder to learn to use. (7) For bevel work the welt should be thin before sewing in. It is the sole that needs to be bevelled to fit the iron. To fit all leathers before using them for their varied purposes is most essential in all parts of boot making.—W. G.

**Filling Lamps—Erratum.**—(See page 93, No. 110.) In line 16, the word "specimen" should be *specification*.

**Junction for Rain-Water Down Pipe.**—J. G. (*Glasgow*).—You have sent, as you say, a half full size model of a rain-water down pipe, 4 in. by 2 in. outside measure, for front of building, intended to go over a return plinth, with 3 in. projection and 3 in. rise. You say that "the block on which it" (your model) "rests shows the rule-of-thumb way we take to get the proper bevel of joints, keeping the centre piece long enough, and by repeated trials arriving at the right thing. This is very unsatisfactory, and takes a long time." Now, what you wish me to do is to show you how to mark out the three portions of piping corresponding with the three pieces of wood, of which your model is formed, accurately and proportionally on a plane surface. This I have done on a scale of one-sixth size in the annexed diagram, and if you mark it out on a piece of zinc, making allowance for overlapping parts beyond the outlines of the three pieces necessary



**Pattern on Flat Surface for Rain-Water Down Pipe to go over Return Plinth, with 3 in. Projection and 3 in. Rise.**

for joining them together, which you, as a practical workman, know how to do, you will arrive at once at the desired result, without any rule-of-thumb trials. First of all, set out on the zinc a central line, and in it take a point C; through this point draw two straight lines, D E, F G, making the angles D C A, B C E, and A C G, F C B respectively, with the line A B. These four angles are angles of 70°, and must be set out in relation to A B with a protractor. Figures in pencil on your model, verified by actual measurement, show that these angles are angles of 70°, but you and others must understand that this angle is not a fixed quantity, but will vary according to the dimensions of the rise and projection over which the pipe may have to pass. Having drawn the straight lines D E and F G through C at the proper inclination to A B, the rest is easy. Draw a straight line from F to E at right angles to A B, and cutting A B in H, and from H set out along this line H K = 2 in., K E = 4 in., and H L = 4 in., L F = 2 in. Through the points K E, L F, draw, parallel to A B, the vertical lines shown in the diagram as passing through these points respectively. The dotted lines through the points L, H, K, show where the zinc is to be bent to form the parts of the pipe. Set out from C, along C B, C M = about 5½ in., and through M draw M P, parallel to C E, and M O parallel to C F. Again, through P draw P N, parallel to C F or M O, and through O draw O N, parallel to C E or M P. Cut out the shaded triangles D C F and G C E, and the shaded equal-sided part O M P N, called in mathematics a rhomb, or rhombus. When the three parts that are left are joined up, and their edges brought into contact, you will find that you have arrived at your junction for rain-water down pipe without much trouble, and no needless waste. Possibly, to some people, this may seem a very long-winded reply, but all plumbers and zinc-workers will know that it is nothing of the sort. Moreover, it is no use whatever to attempt to give a reply on a matter of this kind to a practical man who has been accustomed to work by rule-of-thumb, unless you put it in such a way as will make it perfectly clear to his comprehension. I have said nothing about the horizontal lines passing through A and B. They merely define the extent of the upper and lower pieces in accordance with your model, but practical men will recognise that the limits which they represent may be determined at any length from C and N as may be necessary.—ED.

**Cracked Saw.**—R. W. A. (*London, W.C.*).—The little inequality in the wood should not have caused your accident. You ask whether it is best to break the saw off or to braze it. To break or to try to break it off would be folly, and to braze it you would have to cut the piece straight across first, and then have both ends filed to a bevel before brazing, which would not only reduce the length of the saw, but would spoil the temper for a certain distance, and perhaps render it useless. You did not say how far the crack is from the point. You say it is 2 in.; therefore I judge it to be 2 in. *in length;* but if the crack is not more than 2 in. from the point, and your saw is 28 in. long, should you cut the piece off it will be then the length of an ordinary hand-saw; and if the crack is a little further up from the point, my advice is to cut it off and file the point square, and you will find it useful for some work, and in its place lay out a shilling or two more than you gave for it, and get a good saw. Now, there is a right and a wrong way in cutting off a piece from a saw. If you are not careful, you may ruin your saw. First get a wide chisel in the form of Fig. 1, and grind to an obtuse angle (as shown in Fig. 2), and temper it very hard. Then place the saw on the anvil, with the handle towards you, and the point from you. Take the chisel (holding it straight across the saw, with the head slightly inclined towards you), and strike a blow with a fairly heavy hammer; then move the chisel, and strike another blow, not too heavy, just making a mark with the chisel across the plate. Then go over the same spot again, striking the chisel pretty smartly, taking care to hold the head of chisel a little towards you, or you may get a serious crack or flaw in the plate, and your saw will be of no use. After the piece is off, file the end, and it will not be perceived whether the saw has been cut.—A. R.

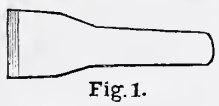


Fig. 1.

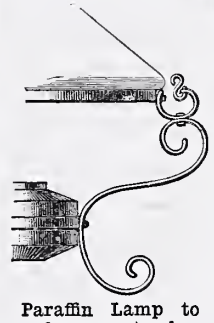
Fig 2.

**Fig. 1.—Wide Chisel.**
**Fig. 2.—Ground Angle.**

**Paraffin Lamps.**—W. W. (*Eastbourne*).—Half in. by ⅛ in. flat wire is strong enough. Have you seen the lamps on p. 696, Vol. II., of WORK? They are made to hang or stand. As sketched, your lamps would be top-heavy. If you do not want to use castings as shown on p. 696, why not shape the side supports as I show in the figure herewith? The piece into which the S hook is inserted is riveted or screwed to the rest of the support, and is thus much more secure than you show in your sketch, in which, apparently, you intend soldering a piece on. Do not put curves of too small a radius, or the metal may break, notwithstanding you may have softened it by heating. To bend it, use, if possible, the tool used by smiths for a similar purpose, which is shaped something like a tuning fork, with short, thick, round prongs sufficiently wide apart to admit the metal to be bent. It is fixed in the hole in the anvil or in the vice, or held in the hand and used as a wrench. If you cannot obtain it or a makeshift substitute, bend the wire over anything round by means of a mallet. Whatever is used to bend, it must not have sharp edges where the metal touches, or nice curves will be impossible. You must give up your evident idea of lifting the lamp with one hand. It is too large for that. If you use hard solder there will be no need to hammer-harden the metal afterwards.—THOMASO.



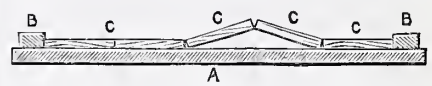
**Paraffin Lamp to hang or stand.**

**Banjo Tailpiece.**—G. C. (*Waltham Cross*).—If you wish to make money out of a patent, it must be something in advance of anything at present in use; if not, instead of being in pocket you will be considerably out of pocket by it. Again, if your article is good, and you can see a chance of making some money with it, patent it yourself. Do not take it to someone, and ask them to buy it from you before patenting it.—J. G. W.

**Violin Varnish.**—W. G. (*Derby*).—The violin must not be stained; the varnish itself should contain the colour. Following the papers on violin making, the subject of violin varnishing will be treated as concisely as possible. I think that anyone requiring only a small quantity of varnish—say, as much as would be required for two or three instruments—would be well advised to buy, rather than make, the varnish. I am at present experimenting with a varnish which is, or will be, in the market, and it gives promise of being successful. As the essential oil of turpentine, which will be the solvent of the gums required for the varnish, does not take up colour in sufficient quantity, it will be necessary to use alcohol as a means of charging the oil with colour. Make a saturated solution of sandal-wood, or any desired colour, and concentrate this solution, by evaporation, to half its original bulk. Mix this concentrated solution with oxidised essential oil of turpentine, and evaporate all the spirit in a water-bath. As alcohol evaporates before reaching the boiling point of water, it will not be necessary for the water to boil. When the little bubbles cease to rise, the spirit will have gone, and the colour will remain in the essential oil. To every ¾ gill of coloured essence, 5½ dr. of mastic tears, 3 dr. of dammar, 5½ dr. of raw linseed oil, and 5½ dr. of roughly-powdered glass; the latter is added to prevent the gums from adhering to the vessel. First put in the mastic, which will take twenty-four or thirty hours to dissolve. Then add the dammar, reduced to powder; this will take about the same length of time. Shake the bottle two or three times a day. Afterwards add the linseed oil; shake a little, and the varnish is made. Let it rest a week or two, and then filter through fine cotton or filter-paper. It must not be used for six or eight months.—B.

**Double Bass.**—BASSO.—A double bass is only a big fiddle, and the materials and method of making are necessarily the same for both, the dimensions only being different. By all means try your hand at fiddle-making before commencing to make a bass. The work is very heavy, the models very cumbrous; and for one instrument the cost in time and materials would run up to something like £20.—B.

**Cramps.**—L. M. (*Lee, Kent*).—The best plan for you to adopt is to plane the edges of the boards accurately; neither cramp nor anything else will make bad joints good ones. Obtain a flat board, larger than your work; on the side, close to the edge, fix firmly a strip of wood; lay the prepared wood on the board, close to the strip; mark the width on the board, and fix another strip, say, ⅛ of an inch nearer to the first strip. You can now, by putting down the outer edges of your boards in contact with the fixed strips, force every joint into close contact by pressing on the boards thus:—



**Cramp Boards.**

When the joints are glued, leave a weight on the boards to prevent the middle rising again. Some precaution is needed to prevent the glue fixing the whole affair together. Some grease or soap will do, but my plan is to lay a strip of paper where each joint will be, and it answers the purpose with little trouble. This mode of gluing is excellent for panels and similar work. L. M. had better get the back numbers in preference to investing in second-hand wooden cramps, as new ones are cheap enough, and there are many hints on cage-making in previous numbers.—B. A. B.

**Colours for Cornice.**—GRADUATE.—The "peculiarity" of distemper colours in drying much lighter is scarcely a thing peculiar to that process of work. If a dry colour is saturated with any colourless liquid, water or oil, the difference is about the same; with *tempera* work, however, we get back the original colour, because the water evaporates off, whereas the oil remains in the form of a semi-transparent film. Flatting paint would to a certain extent meet the case, but even the action of the turpentine evaporating makes an appreciable difference between the colours in the pot and when dry. As, however, flatting should be used almost as a wash, the previous coating, or ground, as it is termed, has to be coloured with a view to assisting the final colour—opacity cannot be ensured by flatting paint alone. Even pure powdered pigments, when used with water or size, undergo the same change. Body colours, as you term them, are simply finely-ground pigments, having sufficient gum or other binding power already added, to dispense with using glue or size. There is no doubt the tints of alabastine, made by the Church Manufacturing Company, would answer your purpose. Were the Company to find a demand for, say, 2 lb. packages for tinting and gesso-work, they would soon meet it. Write for all particulars to 127, Pomeroy Street, London, S.E.—DECORATOR.

**Cleaning a Fox-Skin Carriage Rug.**—A. B. (*Nottingham*).—Take newly-made bran, warm it in a pan over the fire—stirring all the time to prevent burning—and having spread the rug as straight and flat as possible on a table, rub the hot bran well into it for some time. When the fur is sufficiently cleaned, shake and brush the bran out. The cleaning will be done most effectually if the lining and stuffing are first removed. Another way is by moistening bran with hot water, and rubbing it into the fur with a piece of clean flannel; then drying the fur with dry bran and a dry, clean flannel.—M. M.

**Iron Trade Work.**—ONE IN TROUBLE!—I should say: Stick to the fitting. You must allow yourself six or seven years to learn it, instead of two and a half. A good fitter can always be sure of regular and remunerative work. The union will be glad to admit you to membership as soon as you can earn the average wages of the district in which you happen to reside; but not otherwise. It is not

necessary that you should belong to the union in order to obtain a situation.—J.

**Galvanising.**—J. P. (*Handforth*).—Galvanising is a somewhat similar process to tinning; in fact, the only difference is that the articles are dipped in a bath of molten zinc instead of tin. To prepare them for galvanising, the goods are first "pickled" in a tank of sulphuric, or sulphuric and hydrochloric acids mixed, and diluted with water. To quicken the action of this, it is often heated by steam-pipes. When sufficiently clean, they are dipped in killed spirits of salts, and then dipped in the molten zinc, which is covered with a layer of sal-ammoniac. For small things—such as nails, staples, etc.—a sort of cage must be used to dip them in.—R. A.

**Lacquering Brass.**—BRASS.—The address you require for lacquers, etc., is the Frederic Crane Chemical Co., 22, Newhall Hill, Birmingham. Charles Harrop, Esq., is the manager.—R. A.

**Walnut Stain and French Polish.**—W. H. P. (*Birmingham*).—The best French polish for your purpose will be that made by dissolving about 6 oz. of best orange shellac in 1 pint of methylated spirit. A good walnut stain is made as follows: ½ lb. American potash, one pennyworth vandyke brown, one pennyworth nut-galls, a little brown umber, and one gallon of hot water. I strongly advise you not to take your first lessons in polishing on your bookcase; rather try your hand on some plain, flat surface. You will then be enabled to do your bookcase with far more satisfaction to yourself.—LIFEBOAT.

**Varnishing.**—X. Y. Z.—The loss of brilliancy in the varnish might arise from many different causes. I should not think the fault was in the varnish. You should speak to the traveller about it, and hear what he has to say, if you have not already done so. Sometimes it is in the varnish, it being too new; and, on the other hand, using the bottoms or last of the varnish, in which the driers have settled; by standing, this would be likely to cause the trouble. Then, again, the varnish not being sufficiently hard when the carriage is first used; or standing near a manure heap, when the ammonia from the stables will very soon take the brilliancy off the varnish. In many cases the coachman is in fault in washing the carriage instead of sluicing the mud off *whilst it is wet*. Many will leave it till the morning, when it has dried on; then they take the spoke-brush or sponge, and scrub and scour away to get it off; the consequence is, they flat off all the face of the varnish: then the blame falls on to the painter's shoulders. But we must not entirely blame the coachman, as there are some who are very careful in washing off wet mud. I understand you give the vehicle three coats of colour: first, priming, and second of ground colour. You mix them with boiled oil and turps, and sugar-of-lead for driers—you do not give proportions—then two coats of varnish. If you use boiled oil in the first coat of ground-colour you should not use it in the second; that should be mixed with varnish and turps and linseed oil. Sugar-of-lead driers should be used very sparingly. Here seems the cause of mischief. You will seldom find two painters work alike; they each have a different method of working or colour mixing and painting. I would suggest you try the following method, by which I have always found good results, using Noble's or Hoare's and other makers' varnishes. If it is an old vehicle to be repainted, clean off thoroughly with soda and water, touch in all the bare places with lead colour to keep the wet out while you are rubbing down, then rub all the cracks out with pumice-stone and water in the usual way; then paint with a coat of lead colour. This should be mixed thus:—One-third linseed oil to two of turps, mixed with patent driers —½ lb. to a little lampblack, and 3 lbs. of white lead. "Stop up," face off, and sand-paper down in the usual way. The ground or body colour is made with one-third linseed oil to two of turps, and half the quantity of coach-makers' gold size to that of the oil. Second coat is made with no oil; mix body colour with turps and hard carriage varnish in equal parts. Third is a coat of glaze or varnish colour. Now two coats of varnish are laid on—one flatting varnish, the second finishing. This should be a full coat. Let it stand for three or four days before using the carriage. The under coating, or flatting varnish, should be of the same maker's, as varnish of different makers will not always agree, and the best grade finishing varnish cannot impart its wearing quality to worthless under-coating varnish. Are you quite sure your "filling-up" stuff is made properly, and free from red lead? The sum of my suggestions is: never use boiled oil—it is often made up of the worst of oil and driers, only fit to paint fences with, not carriages. Be sparing of driers, as they are corrosive in their action on oils and varnish. Gold-size contains a considerable amount of driers —*i.e.*, sugar-of-lead, sulphate of copper, etc. Turps is a vegetable drier in its action, and always safe to use when mixed with varnish; it should be done while both are warm, to make them blend thoroughly. Give plenty of time for each coat to dry before applying a second coat. Keep the paint-loft at an even temperature, free from draughts, dust, and damp. Remember, water solidifies the surface of varnish; and by washing off the vehicle when varnished, you ensure a hard, lustrous surface, to stand better the action of mud and manure, and the scrubbings to clean off dry mud.—J. C. K.

**Carved Oak Cabinet.**—X. L. U. MAY (*Hebden Bridge, Yorkshire*).—I congratulate you on having made so handsome a piece of furniture from an old oak chest. As the name you give seems to me to be a *nom de plume*, I retain your drawing, until I hear from you again.—ED.

**Razors.**—H. S. (*Oxford*).—If H. S. will refer to Volume II., No. 100, page 782 of "Shop," he will find an article on "How to Set a Razor;" and by reference to Volume III., No. 105, page 7, he will find a short account of "How to Strop a Razor." These two combined will give him, I think, all the information he desires on that subject.—P. B. H.

**Electric Signalling.**—J. H. (*Leigh*).—Electric signalling is generally performed by the telegraph. You will find a popular account of this in Cassell's "Popular Educator." Electric signals may also be made with electric bells; and a system for doing this, arranged by myself, is clearly explained in Mr. Bottone's book, "Electric Bells and all about Them," post free for 3s. from the author, Mr. Bottone, Wallington, Surrey.—G. E. B.

**Corrosive Sublimate.**—AMATEUR TINKER (*St. Austell*).—Corrosive sublimate is sometimes sold under the name of chloride of mercury, sometimes under the name of perchloride of mercury, and sometimes as bichloride of mercury. It may be distinguished from the other chloride of mercury by being soluble in water—1 part of corrosive sublimate being soluble in 16 parts of water—and this forms a saturated solution, as mentioned on p. 714, Vol. II., of WORK. If you get 1 oz. of the corrosive sublimate, and dissolve it in 16 oz. of cold water, it will form a saturated solution. The subchloride of mercury (calomel) is not soluble in water. Corrosive sublimate is a virulent poison.—G. E. B.

**The Praxinoscope.**—A. H. (*Oldham*) thinks that to have the construction of this instrument described would be of interest to the readers of WORK. I could give such a description as he suggests, but I should not be justified in so doing, nor would the readers be justified in working from my description, as M. Reynaud, of Paris, the inventor of the praxinoscope, has patented it in this country. A. H. also asks where pictures for it are to be obtained. He might try the Scientific Toy and General Novelty Co., 14, Cross Street, E.C. Some time since, the shop of Messrs. H. G. Clark & Co., Garrick Street, W.C., was a good place for such matters, but I am under the impression that they are not now at that address.—M. M.

### III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Coal Box.**—W. J. D. (*Earlswood*) writes:—"Will H. B. (*Haydon Bridge*) kindly give dimensions for constructing a coal box to hold a sack (2 cwt.) of coals, as shown in his design, No. 109, Vol. III., page 75?"

[As the plan of one has already been given, W. J. D. should be able to construct a box to suit his own requirements. "Shop" space is too valuable to go on duplicating designs.]

**Model Electric Lights.**—J. H. (*Wolverhampton*) writes:—"Will Mr. Bonney or some reader of WORK kindly tell me where I can obtain the carbon plates for model electric lights, as described in WORK of Nov. 29, 1890; also, if possible, the cost of them?"

### IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Turned Balusters.**—H. (*London, N.*) writes, in reply to F. E. H. (*Lancaster*) (see page 158, Vol. III.):—"The following dealer will supply T. E. H. with price-list of turned, square, and spiral balusters, etc. Address, H. R. Mace, Ekman's Wharf, 33, Wharf Road, City Road, N."

**Petroleum Motors.**—M. (*Bishop Auckland*) writes, in reply to CONSTANT READER (see page 142, Vol. III.):—"These are worked by ordinary petroleum, require no attention while in operation, and can be stopped immediately. As compared with gas engines, they require less cleaning, the valves running for months without cleaning or attention. If you apply to Messrs. Priestman Bros., Holderness Foundry, Hull, they will give you all particulars, being the licensees and manufacturers."

**Cotton Belting.**—J. N. (*York*) writes, in reply to S. A. & Co. (*Stockport*) (see page 158, Vol. III.):—"I have had cotton ropes that run at 56 ft. per minute, and I send him the following recipe: 3 lbs. of tallow, 2½ lbs. black-lead, ¼ lb. beeswax. If a little more grip is required, then add more wax."

**Glossy Ticket Ink.**—W. E. B. (*Peel Causeway*) writes, in reply to A. H. (*Oldham*) (see page 158, Vol. III.):—"The above-mentioned ink can be obtained from Messrs. Brodie & Middleton, 79, Long Acre, London. Red, 6d. per bottle; black, 6d. per bottle; per parcels post, 4½d. extra on each bottle, or on a bottle of each 6d. in all. This ink writes easily, and dries quickly and glossy."

**Fire Balloons.**—H. R. JONES (45, *Barking Road, Canning Town, E.*) writes, in sequence to T. S. (see page 134, Vol. III.), that he is one of the largest fire balloon makers, and that he sells balloons to carry fireworks or parachutes.

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—THE ARTISTS' ALLIANCE; FRETWORK; PUZZLED; F. W. B. (*Huddersfield*); F. W. J. (*Fulham, S.W.*); J. MCN. (*Glasgow*); LONG READER; INQUIRER; HALF-TONE; J. T. N. (*London, N.*); A NEW SUBSCRIBER; JEAN; J. R. M. (*Peckham*); APPRENTICE; J. G. P. (*Woolwich*); F. S. (*Normanton*); B. A. W. (*Croydon*); J. M. (*Manchester*); J. B. (*Salford*); BANJO SLOGGER; A. R. (*Scorrier*); E. W. (*London, W.C.*); G. B. (*Edinburgh*); R. W. (*Bradford*); SILVERSMITH; T. M. (*Birmingham*); L. S. L. (*No Address*); G. B. (*Walthamstow*); C. P. (*Crowborough*); H. J. M. (*Bristol*); T. T. & SONS (*Cardiff*).

ARE universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, Frightful Dreams, and all Nervous and Trembling Sensations, &c. The first dose will give relief in twenty minutes. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

## WORTH A GUINEA A BOX.

For Females of all ages these Pills are invaluable, as a few doses of them carry off all humours, and bring about all that is required. No female should be without them. There is no medicine to be found equal to Beecham's Pills for removing any obstruction or irregularity of the system. If taken according to the directions given with each box, they will soon restore females of all ages to sound and robust health. This has been proved by thousands who have tried them, and found the benefits which are ensured by their use.

For a Weak Stomach, Impaired Digestion, and all Disorders of the Liver, they act like magic, and a few doses will be found to work wonders on the most important organs in the human machine. They strengthen the whole muscular system, restore the long-lost complexion, bring back the keen edge of appetite, and arouse into action with the rosebud of health the whole physical energy of the human frame. These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the Nervous and Debilitated is, BEECHAM'S PILLS *have the largest Sale of any Patent Medicine in the World.*

## Beecham's Magic Cough Pills.

As a Remedy for Coughs in general, Asthma, Bronchial Affections, Hoarseness, Shortness of Breath, Tightness and Oppression of the Chest, Wheezing, &c., these Pills stand unrivalled. They are the best ever offered to the public, and will speedily remove that sense of oppression and difficulty of breathing which nightly deprive the patient of rest. Let any person give BEECHAM'S COUGH PILLS a trial, and the most violent Cough will in a short time be removed.

Prepared only, and sold Wholesale and Retail, by the Proprietor, THOMAS BEECHAM, ST. HELEN'S, LANCASHIRE, in Boxes, 9½d., 1s. 1½d., and 2s. 9d. each.

Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

## An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

[*All Rights reserved.*]

VOL. III.—No. 121.] SATURDAY, JULY 11, 1891. [PRICE ONE PENNY.

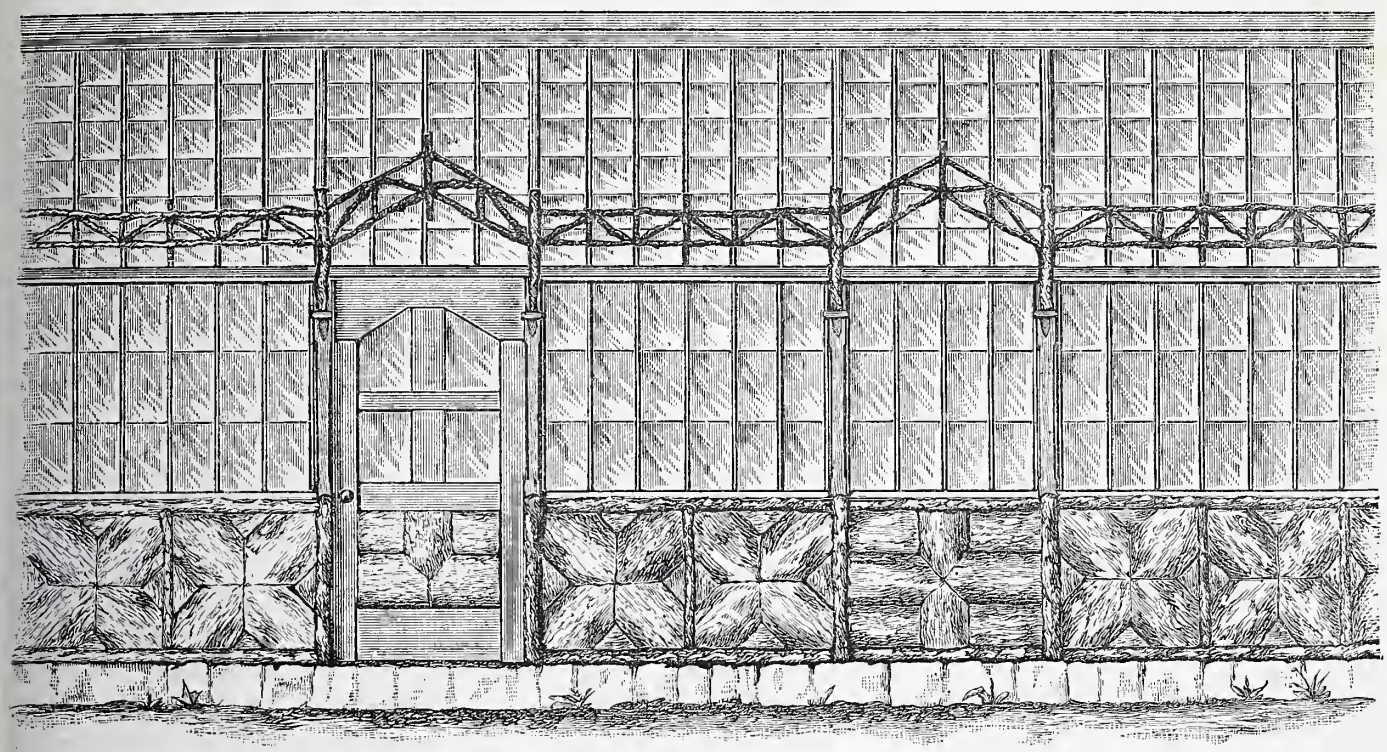

Fig. 1.—Front Elevation of Glazed Rustic Verandah, to be utilised for Grape Culture.

## A GLAZED RUSTIC VERANDAH, TO BE UTILISED FOR GRAPE CULTURE.

BY ARTHUR YORKE.

THE APPLICATION OF RUSTIC-WORK TO GLASS HOUSES — MATERIALS — CONSTRUCTION AND ORNAMENTATION.

*The Application of Rustic-Work to Glass Houses.*—It has been asserted by some who consider themselves authorities in matters of taste that nothing of the nature of a greenhouse ever harmonises with natural surroundings, or is otherwise than an eyesore in a garden in other respects beautiful. This, though rather sweeping, must be admitted to have a certain amount of truth in it. We are all agreed as to the utility of such buildings, and habit has in some sort deadened our perceptions as to their looks; but it must be owned that the hard, straight lines of wood or metal, and wide surfaces of shining glass, are not pleasing, and are too suggestive of the shop and factory to accord well with natural objects; nor have the attempts made to render glass houses ornamental been, as yet, attended with much success.

It has been suggested that the difficulty might be overcome by combining rustic-work with glass. This, at the first glance, looks like a thing which might easily be done; but, on consideration, it will be seen to be otherwise. Rustic carpentry is in its nature irregular, and cannot be brought to those level planes and straight lines essential to glass-work; whilst for interiors, and especially those of houses intended for vines, rough bark-covered surfaces afford too much shelter to insect pests—so that, in reality, rustic-work can only be made applicable to a very limited extent. In the grape-growing verandah before us, therefore, I have introduced a limited amount of rustic-work only, and that on the outside, leaving all within to the plane and the paint-brush.

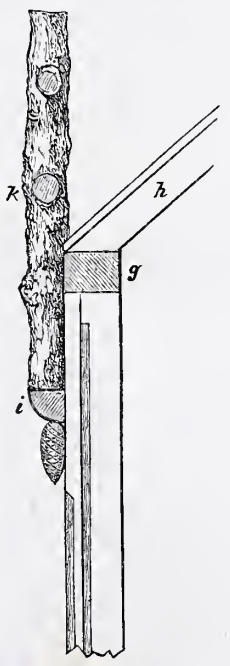

Fig. 3.—Top of Post (side view).

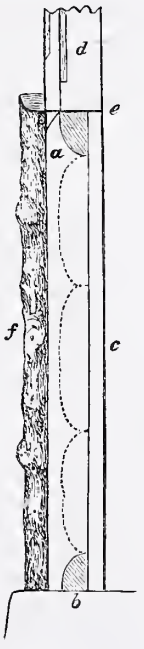

Fig. 2.—Bottom of Post (side view).

*Materials.*—Such of the materials as are of a rustic kind are, for the parapet and uprights, some rather small larch poles or other tolerably straight round stuff, and for the panels, some of those "slabs," or rough outside planks, of which fuller mention was made in my recent paper, "A Model Rustic Tool-house" (page 225). As to the posts, and such parts as are not rustic, they are supposed to be of good deal. The sash-bars, which carry the glass both in roof and walls, are to be bought struck by steam at a lower price than they can be worked by hand, or sashes may be bought ready glazed. For glazing work of this kind, 16 oz., or sometimes 20 oz.,

glass is used, the former, I believe, being generally thought sufficient.

*Construction and Ornamentation.*—As in the design recently given for an open rustic verandah, it is intended that the collar-posts should be set upon and dowelled into a raised platform of masonry. The present structure is, of course, intended for the warmer sides of a house, south or west. The width, to meet particular cases, can be varied, but is, according to the drawings, 4½ ft. The posts are 6 ft. high and 3½ in. square. They are set with spaces between them alternately of 3 ft. and 4½ ft. On their tops rests a wall-plate of the same width as themselves, and 2½ in. deep. The rafters, which are sash-bars rebated to carry the glass, rest on this wall-plate, and against a second vertical one fixed to the house wall.

Fig. 1 is a front elevation of a portion of the verandah, whilst Fig. 2 gives a side view of the lower half of one of the collar-posts. At *a*, in Fig. 2, is seen the section of the upper cross-rail, which has its top 2½ ft. from the ground; at *b* is the lower cross-rail, or sill. Both are of quartered rough stuff, and are mortised to the post ¾ in. from its inner edge, so that when the ¾ in. boarding, *c*, is nailed against them, it will come flush with the inner side of the post. At *d* is indicated the sash-frame, with its rebate for glass, which occupies the upper part of the opening; and at *e* is a metal flashing between rail and sash to throw off rain. It is proposed that the sashes in the narrower openings only should be made to push outwards at bottom for ventilation. At *f* is a piece of halved rough stuff nailed to the front of the post.

The panels, which occupy the lower part of the space between the collar-posts, are filled with pieces of rough plank or "slab," as shown in Fig. 1. These pieces should wear their natural bark as far as possible; they are nailed to the inner boarding.

In Fig. 3 the upper part of a post is in like manner shown in profile: *g* is the wall-plate in section, and *h* is the lower end of a rafter. At *i* will be observed a strip of quartered stuff nailed across the post (with a fir-cone bradded beneath it), which gives a starting-point to the upright *k*, by which the openwork rustic parapet is supported. These uprights are of small round stuff, slightly flattened on the side towards the post. The openwork parapet is too plainly figured to need description; it is intended to break to a certain extent the straight lines, and partially to conceal the glass-work of the roof, without seriously interfering with sunshine.

So much of the planed wood-work as shows outside should be painted of a good brown, to assimilate with the rustic-work; in the interior the time-honoured white or drab paint will probably hold its place. But internal arrangement—and, indeed, everything which is purely greenhouse construction—is beyond my province, such matters having already been ably treated in WORK. (See the Articles at p. 177, Vol. I., etc., to which I refer the reader.)

Of the illustrations, Fig. 1 is drawn ½ in. to the foot, whilst Figs. 2 and 3 are on a 1 in. scale. Of course it must be borne in mind that these are somewhat small for practical work, and that the reader, before he begins to carry out the idea, should make a working drawing on a larger scale, after having made such modifications in the structure as circumstances may suggest as being desirable.

## HOW TO MAKE DRAWERS SLIDE EASILY AND TRUE.

BY E. W.

DRAWERS THAT JAM AND THE CAUSE OF JAMMING—IRREGULAR AND UNUSUAL SHAPES—HOW TO OVERCOME THE DIFFICULTIES ARISING FROM UNFAVOURABLE PROPORTIONS OR IRREGULARITY OF FORM.

*Drawers that Jam and the Cause of Jamming.*—Everybody knows how troublesome some drawers are to move in or out; they seem as if endowed with a prodigious amount of mechanical perversity; first they jam at one end, and then at the other, occasioning at times considerable exasperation of spirit, and I fear that not a few regretable outbursts of profanity may be traced to this cause. It will almost invariably be found that the drawers that give so much trouble have fronts that are long in proportion to the length of the sides, though at times the trouble is wholly, or partly, due to the particular form of the drawer. In well-made and well-fitted drawers, the liability to jam is not so great as with those loosely

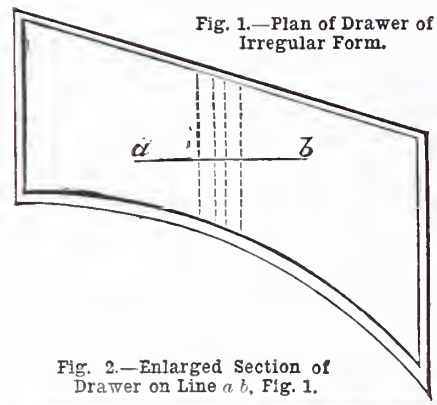

Fig. 1.—Plan of Drawer of Irregular Form.

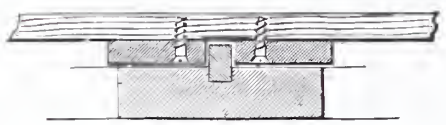

Fig. 2.—Enlarged Section of Drawer on Line *a b*, Fig. 1.

thrown together to sell; but however well made and fitted, drawers of the character referred to are very apt to stick fast by jamming endways, if unequal opening or closing force be applied at the two ends, especially so when the drawer has been drawn well out and but a small portion is within the case. This difficulty may easily be got over by a very simple device that I have found to work well, and that deserves to be generally known.

*Irregular and Unusual Shapes.*—Fig. 1 is the plan of a drawer I once had to make for a circular corner of a counter, and this, it will be seen at a glance, is of a form that, under ordinary circumstances, would prove a continual source of annoyance to those whose lot it would be to use it. It was this case that led me to specially consider the conditions necessary to secure free and easy running of drawers in particular, and sliding bodies in general, and finally to the adoption of the following method of treatment for all drawers of troublesome form or proportion.

*How to Overcome the Difficulty.*—Across the bottom of the drawer, from front to back, and parallel to the sides, a narrow groove is formed, that may be in any convenient position, but preferably in mid-length, and such that a hardwood tongue or fillet, fixed to a transverse rail of the framework below the drawer, can freely slide therein.

The drawer, Fig. 1, was joiner-made, and consequently minus the centre rail in bottom that a cabinet-maker would in this case have put, and wherein a groove might with advantage have been ploughed. A couple of fillets were, therefore, glued and screwed to the bottom, as shown by the dotted lines, Fig. 1, and the enlarged section at *a b*, Fig. 2. This answered admirably, and made the drawer the nicest working one in the whole place.

## HOW TO MAKE A QUARTER HORSE-POWER STEAM ENGINE.

BY F. A. M.

### BORING THE CYLINDER.

DESCRIPTION OF WORKING DRAWINGS—MAKING THE BORING-BAR AND CUTTER—FIXING CYLINDER CASTING ON SADDLE—SPEED AND FEED—OTHER WAYS OF BORING—TURNING THE FLANGES AND ENLARGING THE ENDS OF BORE—TURNING THE CYLINDER COVERS AND SCREWING THE STUFFING-BOX AND GLAND.

*Construction of Engine.*—Fig. 4 is the elevation of our engine; and Fig. 5, the plan. Fig. 6 shows the back view, and Figs. 7-29, the various details, the most important dimensions being marked in figures, as is done in engineers' workshops. These, making a full page of cuts, will appear in the next article. Paper expands and contracts slightly, according to the weather; so that, besides the trouble of measuring the drawings with the rule, such measurements are never to be depended on; whereas, when the draughtsman has written the dimension upon the drawing in feet and inches, it is read at a glance without measuring, and reads always the same. It is usual, instead of writing "ft." or "in." upon the drawing, to designate feet by one dash or accent and inches by two: thus, 2 ft. 3 in. would be written 2′ 3″, the figures being placed about the middle of a blue or dotted line extending the whole distance measured, and terminating in an arrow-head at each end.

The writer well remembers seeing, some ten years ago, working drawings of a small power engine similar to Figs. 4 and 5, but smaller and less complete, which drawings were offered for sale with the requisite castings and other materials. The charge for the drawings alone (lithographed) was one guinea. Now, however, such drawings can be obtained at about two shillings, without, however, showing pump or governor. It is believed that these plans now offered to the readers of WORK surpass any hitherto published in completeness and fulness of detail, every important part having been drawn out separately, as is usual with larger engines in engineers' works. The facilities usually possessed by amateurs have been considered, and slight departures have been made from the usual practice (when that could be done without injury) in order to simplify the work.

It is a great satisfaction to the present writer to know that the design has the approval of J. H., and that Olla Podrida will probably write on a boiler of suitable size.

Looking at Figs. 4 and 5, it will be seen that the cylinder overhangs the bed-plate, which latter is cast with a round flange at the back end, against which the front cover of the cylinder is bolted; thus the length of bed-plate which would have extended under the cylinder is dispensed with, as also the

feet, which would have had to be cast on the cylinder. A small amount of fitting is saved, and some weight of metal; moreover, the cylinder, being attached by one end only, is free to expand lengthways when heated by the steam.

Taking in hand the cylinder first of all, it should be bored with a bar, which will require a slide or self-acting lathe. Possibly a boring-bar to bore a 2 in. cylinder 5½ in. long may be borrowed from a neighbouring shop, or hired; but we will suppose it must be made. Get from the blacksmith a piece of 1¼ in. round iron 14 in. long; make him square the ends, to save you filing, and then take it to your lathe, and after centring it rather deeply, finish the ends and turn it up true. It will now be about 1¼ in. diameter. At its middle, scratch two fine lines round the bar with a point tool, ⅞ in. apart; between these lines and through the middle of the bar a hole or slot must be cut, ⅞ in. long and $\frac{3}{16}$ in. wide, to take the cutter and wedge. To do this, we must first mark the position of the hole on both sides, the marks being exactly opposite, so as to ensure that the cutters shall pass through the middle. Wrap a slip of paper round the bar, and cut it so that it will just meet; by folding this in half, we can measure half round the bar. Take $\frac{3}{16}$ in. in the dividers, and mark that distance off upon one of the lines marked on the middle of the bar; measure half round with the folded paper, mark two other spots on the other side of the bar, and indent these marks with a centre-punch. To draw four lines from each of these four points, parallel with the bar and with each other, we must use the point of a tool held in the slide-rest, the work being held still by advancing the back-centre by its screw so as to jam the bar between the centres. A point tool turned over to lie on its side will do this best; the bar would be turned round till the dots of the centre-punch come to the point of the tool; the screw of the back-centre would then be forced a little, to prevent the bar from turning; and the tool moved sideways by the screw of the rest after advancing it to touch will mark the lines. Fig. 30 will make this quite plain.

Having marked the place for the hole on both sides, we must now remove as much of the material as possible by drilling with a $\frac{3}{16}$ in. drill, boring half-way through, first from one side and then from the other, and placing the holes so as almost to cut into one another. A narrow cross-cut chisel will now be used to cut out the metal between the holes, and the hole will then be finished by filing, cutting away just up to the lines at both sides, and trying to keep the sides and ends of the hole flat, and not rounded; which is a rather difficult matter. Several such holes will have to be cut in the course of our work; it will be well, then, to do our best with this one without being discouraged, though it is not a very easy job. Now obtain for the cutter and wedge two pieces of tool steel ½ in. wide, $\frac{3}{16}$ in. full thick, and 2½ in. long. File these up, flatways first, to exactly $\frac{3}{16}$ in. in thickness, trying them with the callipers to ensure their being the same thickness throughout, and trying them in the slotted hole; when you can get them in about ⅛ in., file them no thinner, but fit the hole to them. This is done because, in spite of the utmost care, the sides of the slot are sure to prove round, causing the hole to be wider at each end than in the middle, which you will find out as soon as you try to push in the slips of steel. Your efforts then should be directed to filing away the metal in the middle, without enlarging the mouths of the hole, and this must be continued until the wedge and cutter can be pressed in with the fingers. It will greatly help in filing the sides of the hole flat if the bar be placed between the centres of the lathe, and filed while free to turn on its own axis. Now square up one edge of each of the pieces of steel, round the corners a little, and use them to finish the ends of the slot, carefully filing them out till the steel pieces will bed down solidly upon either end. Fig. 31 is a section through the bar, showing the cutter and wedge in position; and Fig. 32 is an end view. The cutter may now have the shallow notch filed in one edge, but this notch is not so wide as the diameter of the bar, because there must be a small flat filed across the mouths of the hole on each side of the bar, so that the shoulders of the notch on the cutter may bed down on the flats so formed, and not on the round surface (Fig. 32 shows these flats). The cutter having been well fitted, so that it requires pressure to force it into place, its back may now be filed across and tapered to suit the wedge; a workman would know by instinct how much taper to give so that the wedge may not jar loose in working, but the amateur had better go by rule; and the rule for the taper of "fast" keys is ¼ in. per foot=$\frac{1}{16}$ in. in 3 in.; since, then, our cutter is 2 in. long, the width at one end should be less than that at the other by $\frac{3}{64}$ in., or, say, $\frac{1}{16}$ in. bare. Having thus finished filing up the cutter, file up the edges of the wedge, making sure that it fits the whole length of the hole, and not merely at one end; then shorten its ends as in Fig. 31, put the cutter in position, drive in the wedge firmly, put the bar in the lathe, and turn up the ends of the cutter till it measures 2 in. long; take also a cut down the front or cutting edges of the cutter, to ensure those edges being true. The cutter must now be removed from the bar, but before doing so, be careful to mark both it and the bar, so that you may be able to put it back the same way, otherwise all your trouble in turning it will have been wasted. Having taken out the cutter, proceed to "back off" the cutting edges with the file; these edges which do the work are marked *a*, *b*, in Fig. 31. In Fig. 32 the letters *a*, *b*, are placed close to the leading or sharp edge. The file must slope the cutter back from these edges, so that they may have a cutting angle of about 80°. The edges will have to slant in contrary directions, and in doing this "backing off" be careful to leave just a trace of the tool-marks left by turning so as to ensure that the edges shall cut equally. Having finished the cutting edges, proceed to back off the guiding or scraping edges, *c*, *d*, removing rather less in this case than in the first, and the cutter will be ready for hardening. Any fire will do for this, provided there be a good amount of red coals; twist a piece of stiff iron wire round the cutter, leaving a foot or so of the wire for a handle; have about a quart or so of water ready, which may be slightly warm, and when the cutter is thoroughly and equally red, plunge it endways into the water, and leave it a minute. Now take out and try with a file, when, if quite hard, it is to be taken to the grindstone, and the edge slightly ground: it does not require to be "let down" or tempered, because the edge being 80°, it is quite strong enough without, and, thus treated, it will go right through the cylinder without showing any sign of wear, coming out as sharp as it went in. The boring-bar and wedge are very likely to come in useful for other work, as many cutters may be made for it of different lengths, so as to bore holes from 1½ in. to 2½ in. in diameter.

The next thing will be to secure the cylinder casting upon the saddle in such a way that its centre line may be true with that of the lathe centres. Figs. 33 and 34 show one way of doing this, which may perhaps suit the majority, though each will have to manage so as best to suit his own lathe. The upper part of the slide-rest is supposed to have been removed, and in its place is bolted a flat plate of iron from ¼ in. to ½ in. thick; two pairs of wooden clamps are prepared to fit the cylinder, and bored through for the four holding-down bolts, made of ¼ in. round iron, tapped into the square plate at their lower ends, and fitted with nuts and washers at the top. Our aim here will be to cut away the lower clamps by degrees till the cylinder comes level at the exact height of centres; it can be taken out of twist by slacking the two holding-down bolts, and turning round the square plate, A, which plate will require to be hammered fairly flat by the blacksmith, and it must have two thoroughfare holes in it to pass the holding-down bolts which secure it upon the slide, as well as the four tapped holes which receive the ends of the bolts which secure the wood clamps. The side on which the plate A is bolted would be fixed by tightening the screws of the gib *b*.

Having fixed the cylinder firmly in position, so that the boring-bar occupies the centre of the hole at both ends of the cylinder, put the cutter into the slot in the bar, and fix it with the wedge so that it presents its two cutting edges towards the hole; put on the requisite change wheels to give a feed of about seventy to eighty cuts to the inch; put in the back gear with the band on a slow speed, to give about one turn of the bar to three or four treads, and you are ready at last to begin cutting. This cut should be carried right through without stopping, and it will take perhaps about half an hour. It will be well, therefore, to oil up the lathe before you begin, and to choose a time when you are not likely to be interrupted; the lathe should drive easily, and the cutter should remove an equal amount of metal all round, and take off as much with one edge as with the other. The cylinder casting will soon get pretty warm under the cutting, which will cause it slightly to expand in size; if the cutting were stopped for long, so that the metal began to cool, there would be produced a slight groove or inequality in the bore quite perceptible to the finger. This suggests that it would be an additional precaution, just before beginning to cut, to slightly warm the casting, which could be done equally all round by holding inside it a red-hot poker till it felt warm to the hand, then replacing the bar, and beginning to work at once. The cutter can take a cut of $\frac{1}{16}$ in. all round, and one cut should be enough to finish the bore, leaving a fine surface, bright and smooth, and perfectly parallel. If it is not so, and for any cause it were necessary to take another cut, the cylinder would be left as it is whilst another cutter was made a little larger than the first, to bore, say, 2⅛ in.

As soon as the cylinder is removed from the lathe, rub it out carefully with an oily rag, to clean and preserve it from rust, and examine the bore on the side of the port-ways: for it is possible, unfortunately, that the boring may expose a blowhole in the casting, making a communication between

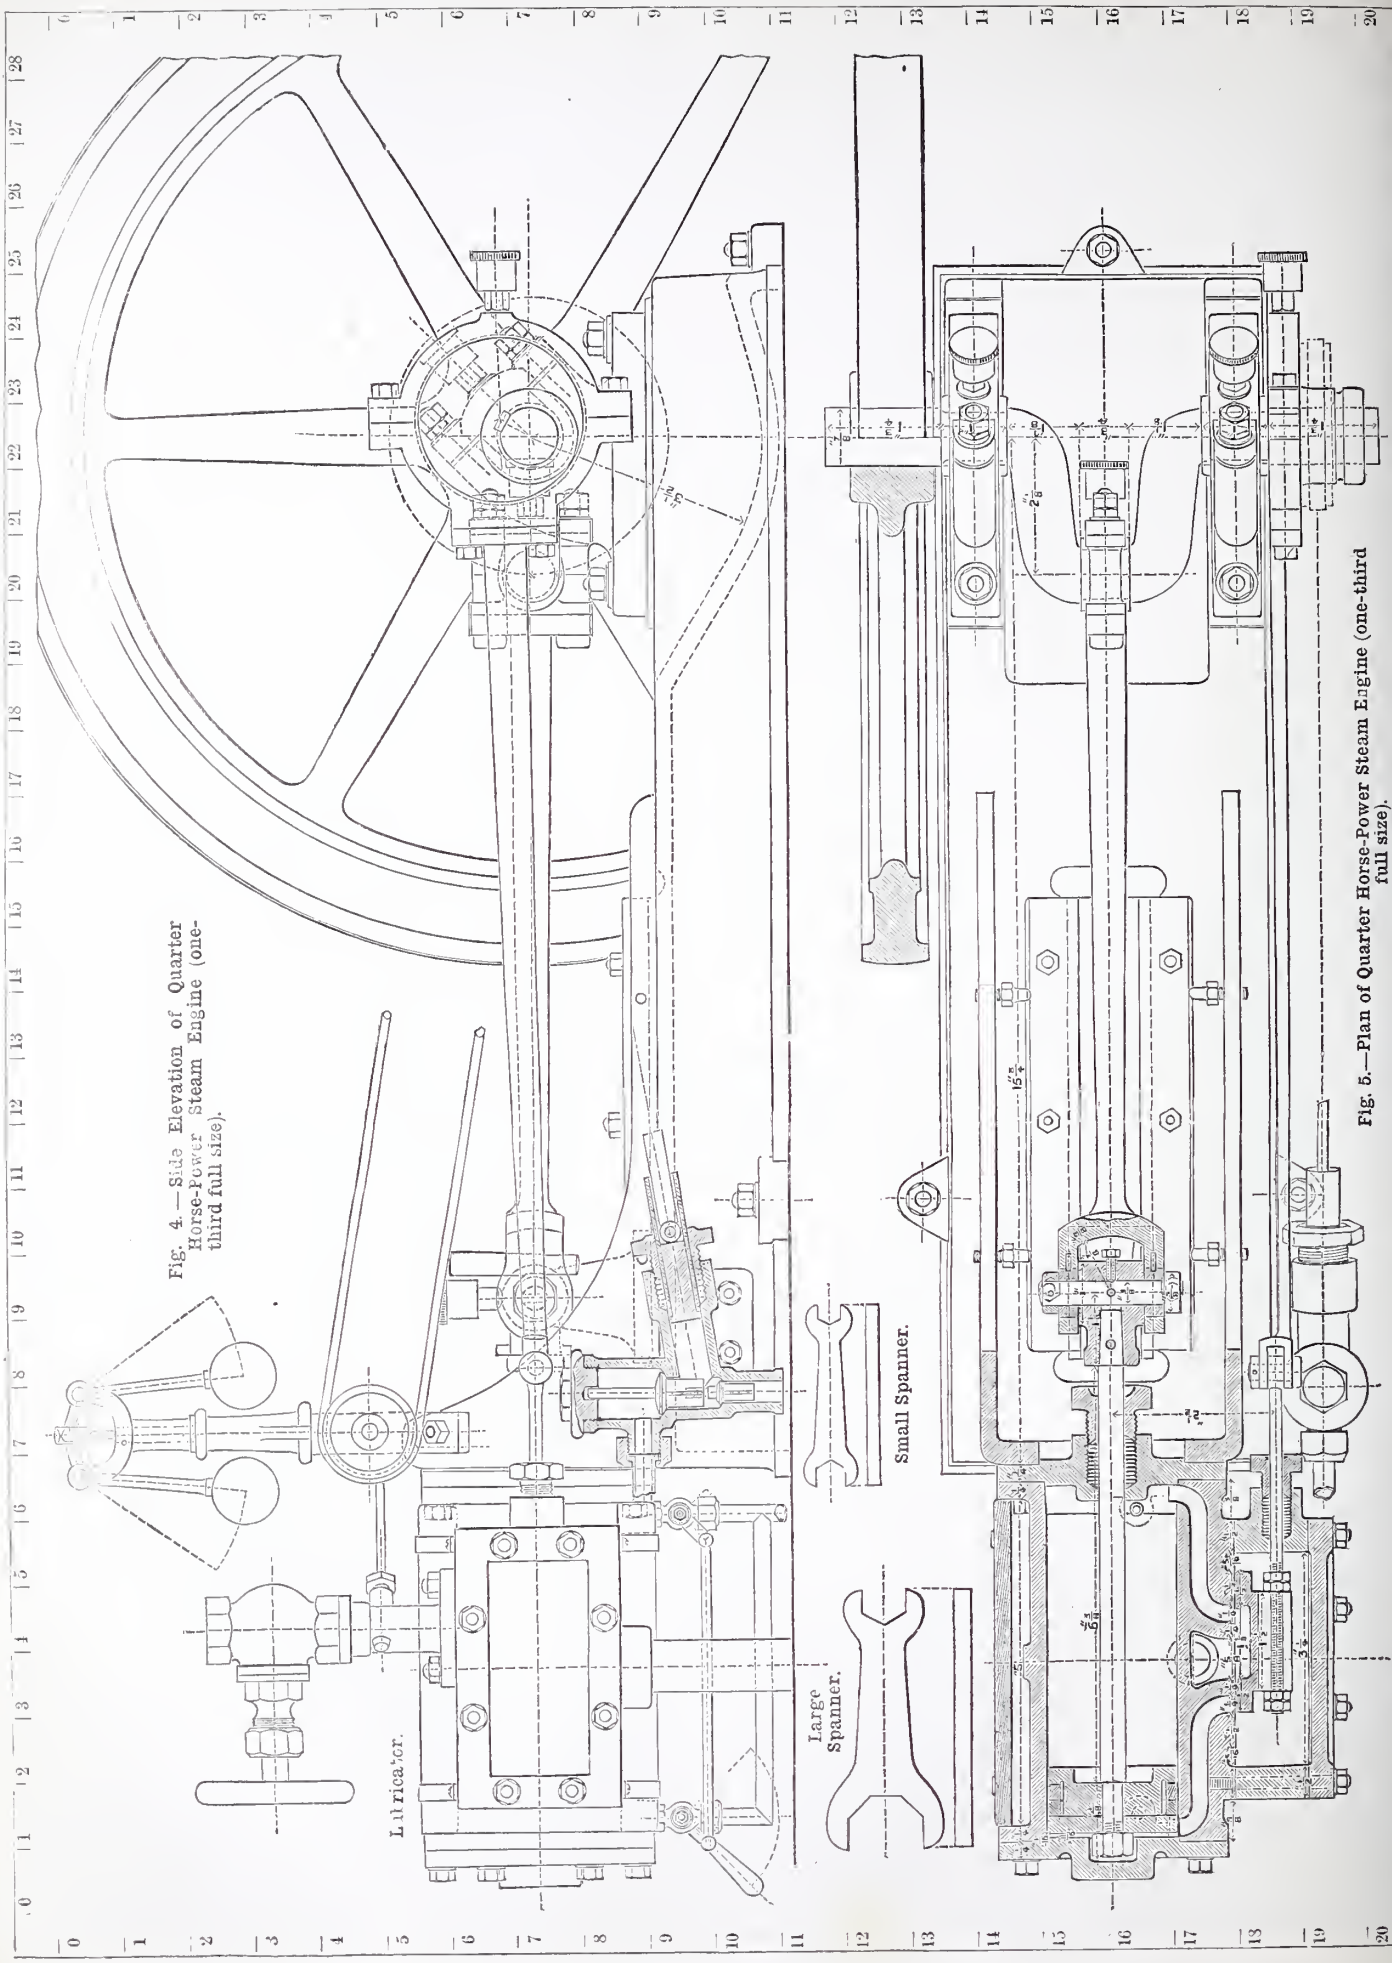

Fig. 4.—Side Elevation of Quarter Horse-Power Steam Engine (one-third full size).

Fig. 5.—Plan of Quarter Horse-Power Steam Engine (one-third full size).

the inside of the cylinder and the port. If the blowhole is a bad one that you cannot stop by screwing in a little plug with red lead, the casting should be returned for another.

But what, it may be asked, are those to do who have only a slide-rest, and no self-acting lathe, with a saddle, on which the cylinder casting can be bolted? Without going into details, it may be said that if the slide-rest have a traverse of at least 5½ in., and the mandrel of the lathe be strong and not too short, the cylinder might be mounted upon the face-plate, and bored with a strong inside tool of about 1 in. square. The cylinder, however, will stand over-neck a good deal, and so will the tool. Perhaps a strongly built 6 in. or 7 in. lathe might do the work tolerably well. The hole would be made slightly larger at the mouth, and then carefully corrected until a solid gauge, made something like the piston and rod, will fit perfectly all the way down. Yet another way would be to use a couple of flat drills, such as would be used for boring a pulley or other hole in cast iron; and this could be done by one who had no slide-rest: both these plans would produce inferior work, and would render necessary the use of a grinder to finish the bore true and smooth; moreover, a person who wished to make up this engine without having a slide-rest, ought first to begin by making himself a slide-rest, or he will find himself most seriously embarassed further on. The reader will pardon so lengthy a description of this first stage in our work when he understands that the greater part of the friction of the engine is due to the piston, and that any want of truth and perfection here would cause serious waste of power and steam. Let him, then, not try to hurry his part, but rather to do it well; it may take three days to make the boring-bar and cutter and to fix the cylinder in position, although the actual boring can be quickly done.

The next operation will be to turn the flanges of the cylinder true with the bore, and to slightly cone out the bore at each end for ½ in. (See the section of the cylinder in Fig. 5.) This is done so that the packing rings of the piston may pass beyond the surface on which they rub; if it were not so, they might wear a slight depression in working, and leave a ridge at each end of the bore, which would make it impossible to get them out. This precaution is always taken in similar cases; as, for instance, in the slide-valve and the slipper guide. We have then to chuck the cylinder true with the bore, so that a flange and part of the bore shall be accessible to the tools. Fig. 35 will show how this can be done. Obtain a piece of round iron, about a foot long, which you can turn up to a diameter of 2 in.; reduce it carefully till you can drive on the cylinder to within about an inch of one end; now you can turn up one flange, and also enlarge the bore by slightly coning it out at that end. When this is done, drive off the cylinder, and drive it on the other way, so as to treat the other end in the same manner. M is the mandrel; D the driver chuck; P a pin driven or screwed into the mandrel to catch the arm of the chuck, in case the workman has no 2 in. carrier. The cylinder must not be driven on very hard, or it may burst. Do not grudge the iron for the mandrel, as it is very likely to come in useful again; turners have quantities of such, of all sizes.

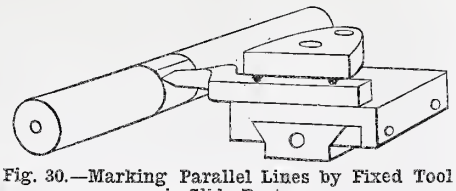

Fig. 30.—Marking Parallel Lines by Fixed Tool in Slide-Rest.

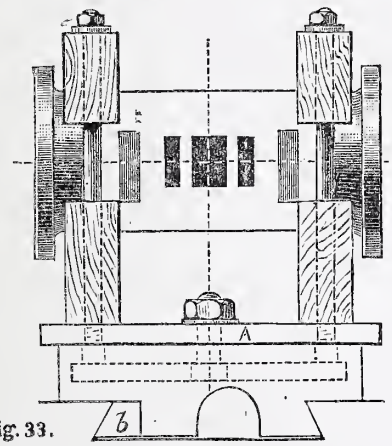

Fig. 33.

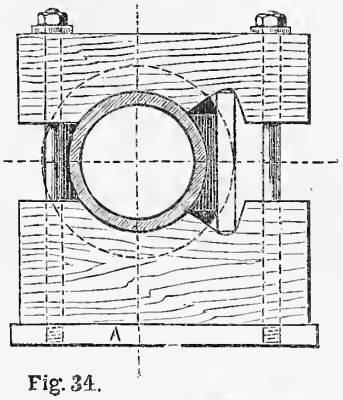

Fig. 34.

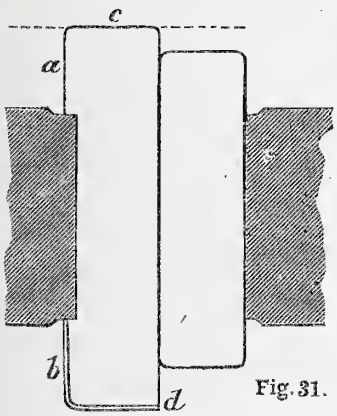

Fig. 31.

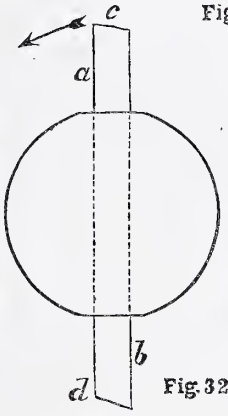

Fig. 32.

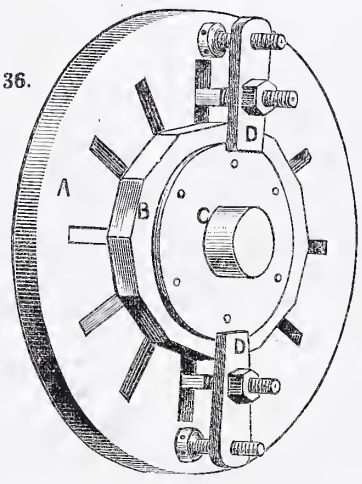

Fig. 36.

Fig. 31.—Section through Centre of Boring-Bar, showing Cutter and Wedge. Fig. 32.—End View of Bar. Fig. 33.—Cylinder Casting fixed ready for boring with Bar. Fig. 34.—End View. Fig. 36.—Cylinder Cover chucked for Turning.

Taking in hand now the cylinder covers, begin with the bottom cover. An American universal chuck will hold it by the outer edge, or it may be driven into a recess in a piece of hard wood turned out to receive it. Face up the inside surface of the cover flat and true, and make the shallow projection fit exactly into the back end of the cylinder, trying this on to it as it is fixed in the chuck; then with a point tool strike a fine circle 3 in. diameter, to indicate the centres of the six screw holes; mark the positions of these with the centre-punch, not omitting to notice that, whilst four holes equally divide the circle into sixths, one pair are placed further apart by ⅜ in., to avoid clashing with the ports. Lay aside the bottom cover, and take the top, or lid, which has the stuffing-box cast on it; turn up the inside in the same way as the other, fitting it to the other end of the cylinder—that is, the front end; and, after striking the 3 in. circle for the screw holes, bore a ⅜ in. hole truly through the centre of the boss for the piston-rod to pass through. By boring this hole carefully *at the same chucking* as the cylinder fitting, you ensure that the piston-rod shall be exactly in the centre of the bore of the cylinder. Next bore the six holes in the two covers with a drill $\frac{3}{16}$ in. full. To turn the other side of the covers and their rims true with the part already finished, a recess must be made in a hard wood chuck, into which the cylinder fitting on each lid can exactly fit; in making this recess, try each cover in, and begin with whichever has the smallest fitting, because then the recess can be slightly enlarged for the other. Having fitted one cover into the chuck of hard wood (which is supposed to be screwed to the front of a face-plate), place two or three dogs to clasp it firmly by its edge against the front of the wood chuck. Fig. 36 shows the face-plate, A, and the wood chuck, B, of beech, or some wood equally hard, secured by wood screws passing through from the back of the face-plate. B is carefully faced up level, and then the half-turned casting, C, is pressed into a recess turned in the wood to fit the shallow projection, after which the dogs, D, D, are applied to secure and hold it fast, grasping it by the extreme edge, so as to allow the tools to face up almost all the front surface. In the case of the front cover, the shallow fitting on the outside of the cover (Fig. 5) will be formed, and the stuffing-box will be bored, and screwed about 14 pitch, with the screwing lathe; or a ⅜ in. gas-thread tap might be used, followed by a chaser, by those who do not possess a self-acting lathe. Finish both covers nicely, and polish with emery-cloth, and, before removing either from the chuck, turn up and

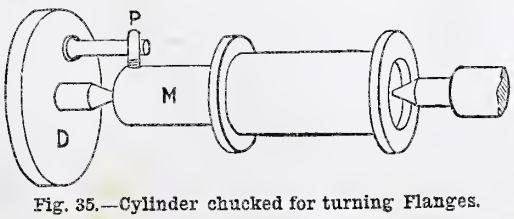

Fig. 35.—Cylinder chucked for turning Flanges.

polish their edges to exactly the size of the flanges on the cylinder. To do this, we must remove the dogs, and secure the cover to the chuck by two or three wood screws, passed through the screw holes in the covers into the wood chuck; this method of holding will also allow of finishing the edge of the face of the covers, which could not be touched while the dogs were in position. To complete the cover, take the brass casting for the gland, bore it with a $\frac{3}{8}$ in. hole while chucked in the lathe, mount it on a small mandrel, turn up and screw it with a point tool in the screwing lathe, finishing with a chaser to fit the internal thread in the cover. The screwing lathe will ensure a true thread, but the screw might be marked out by the $\frac{3}{4}$ in. gas stock and dies corresponding to the tap which might have been used to start the thread in the cover, when the chaser would be used afterwards to finish: thus both these screws can be accomplished without a screwing lathe, even by an amateur, who cannot cut them with the chaser alone; but it is not likely they would be very true or correct. All screws of this kind should be cut first in the screwing lathe, and then they may be finished to size and shape by the chaser or the stock and dies. The top of the gland is formed into eight equal sides, that it may be grasped by a spanner. The best way to do this would be by means of a division-plate on the lathe pulley, but, failing this, a template or pattern may be made by drawing the required octagon on tin or sheet metal, and after cutting away the inside and filing to the lines, the template can be used to test the sides of the gland as they are gradually filed to shape. The same template will serve for filing up the pump gland, as that is the same size, to suit the same spanner. Another equally good method would be to file up a little octagon in tin, and use that to file out the spanner (shown with another in Fig. 5); the jaws of this largest spanner being thus correctly shaped, it can itself be used to test the octagons on the piston-rod and pump glands: the smaller end of the same spanner is for use on the six-sided valve-rod gland, union on pump delivery, and cap on pump valve-box.

## PICTURE-FRAME GILDING.

BY H. E. MAXTED.

INTRODUCTION—GILDER'S CUSHION, KNIFE, TIP, ETC.—GILDER'S MATERIALS—COMPO.—PARCHMENT SIZE—THIN WHITE—THICK WHITE—CLAY—CLEAR-COAT—MATT GOLD-SIZE—BURNISH GOLD-SIZE—OIL GOLD-SIZE—GILDER'S ORMOLU—MATCHING MOULDINGS—OIL GILDING — BURNISHING — BURNISHERS — GILDING FLATS—RUBBING DOWN MITRES—RE-GILDING.

THE art of gilding, as applied to picture-frames and numerous other articles of interior decoration, requires not a little care and skill to be exercised by the operator, professional or non-professional. The latter presumably possesses a good stock of patience and liking for the work in hand, which should go a great way to balance the experience of the former.

In a back number of WORK, under the title of "Plain and Decorative House Painting," the gilder's cushion, knife, tip, etc., were illustrated and explained; it is therefore quite unnecessary to comment upon them again. In addition to these, some tools are requisite, but they are inexpensive and few. A badger, two or three small sash tools, camel's-hair pencils, and stone jars or pots are all that are absolutely necessary at present.

Before going further into detail, it will be advisable to describe in full the numerous preparations used in picture-frame gilding, so that reference can be made to them in their order as we proceed. First of all, the reader must be impressed with the importance of using clean pots and brushes, keeping all free from dust or dirt of any kind, and not using size when it begins to turn bad. This is scrupulously carried out by the practical man, and materially assists in the production of successful work.

Gilder's materials can be procured from Brodie and Middleton, Long Acre, Rowney, Rathbone Place, or any artists' colourman, and will require to be mixed in the following manner:—

*Compo.*—Boil seven pounds best glue in seven half-pints of water; melt three pounds of white resin in three pints of raw linseed oil. When well boiled, mix together in a large saucepan, and boil for about half an hour. When done, pour into a boxful of well sifted and rolled whiting. Mix all together, and knead up like dough till it will hold no more whiting. To keep it moist, wrap up in a damp cloth, or bury it in whiting.

*Parchment Size.*—Wash a handful of fine parchment cuttings in a clean saucepan or other suitable vessel, cover with water, and simmer for two or three hours until the water has evaporated to one-third or one-fourth of its original volume. To test if it is strong enough, the hand should be wetted with the size, the other hand being pressed closely to it. If it is found to be sticky, strain the solution off into a clean jar to cool, and save the parchment to be boiled up again.

This size is used to mix nearly all the preparations required by the gilder, and should, when cold, be a firm jelly; the stronger it is, of course, the firmer it will set, and consequently will require water to be added in some of the preparations.

*Thin White.*—Parchment size, moderately strong, mixed with rolled whiting and strained through muslin. This must not be too thick.

*Thick White.*—The same as preceding, with enough whiting to make it thick like cream.

*Clay.*—When unmixed is very stiff. Place a small quantity of size in a clean stone pot, add a little water, melt, and add a small portion of clay; stir till dissolved, and add more clay till it is of the consistency of cream.

*Clear-Coat.*—Take a tallow candle, light, and drop two drops in a pot of moderately strong size. The grease will keep it from working up.

*Matt Gold-Size.*—This is mixed in the same way as clay, but slightly weaker, and is of a reddish tinge.

*Burnish Gold-Size.*—Mixed the same as clay, but weaker, and is of a bluish tinge.

*Oil Gold-Size.*—This is bought ready for use or unmixed; if the latter, it must be thinned out with boiled linseed oil and fat oil. A little patent driers will hasten its drying qualities, which should take place in about twelve hours.

*Gilder's Ormolu.*—There are many recipes for this preparation, but equal parts of white lacquer and methylated spirits (mixed and kept in a bottle) are often used, a few drops being put into the finish size, which is applied after the gold is laid.

Now that we are acquainted with the preparations that will be used, I propose to gild a frame, compo.-faced, Alhambra pattern, with compo. corners, and flat inside.

The practical man has sometimes to match certain mouldings not easily procured, and consequently has to prepare them from the wood; but this is seldom done now, as they can be bought in the white, or compo.-faced and whitened up ready to prepare for gilding, at much less cost than he could make them in small quantities. So if the reader will follow, I will endeavour to explain concisely the art of frame gilding, which of course will embrace furniture gilding, such as chairs, tables, cabinets, or other interior work.

There are two methods of gilding—namely, oil for ornamental work, water for flat or burnished work.

To gild a frame in oil with bead and prominent parts burnished, first wash the ornaments, such as corners or top and bottom ornaments, to free them from grease or dust that will adhere in getting them from the mould. Cold water and a brush must be used—with not too much friction, or the sharpness of the lines may be destroyed. After this is dry, lay a coat of thin white evenly on the frame, applied hot, taking care not to float it or put too much on, but only to cover every part. When dry, take some powdered whiting and hot size, and mix a little of each with a gilding knife or modelling tool; the predominance of whiting will make putty. Then thoroughly overhaul the frame and stop up every defect in the moulding, nail-holes, and corners that are damaged. When this is hard, it must be glass-papered—the flats, hollows, and beads with fine glass-paper, taking care that no defect is overlooked, for the success of our work depends upon the absolute perfection of each smoothing down.

After dusting, it is ready for a coat of clay; but, before this is applied, the parts to be burnished must be determined, and three coats of thick white laid evenly on and glass-papered. Clay should be applied hot, in the same way as thin white, not forgetting to cover every part of the frame, dabbing the brush down into all ornamental parts, and getting well into the bottoms.

When this is dry it is again ready for smoothing with fine emery-paper, which should produce a smooth, even surface, for the frame will not be papered again.

Now attention must be paid to the burnishes. Matt gold-size is mixed and applied three or four times evenly with camel's-hair pencil. When dry, paper with fine emery, and brush off with a damp sponge.

After well dusting, give the frame two coats of clear-coat, moderately strong, touching every portion carefully, as it is intended to keep the next preparation from sinking into the frame, but do not put it on too abundantly. A good way is to squeeze the brush out every time between the fingers before applying it, and the frame will receive a thin level coat all over, without running. When this is dry the work is ready for oil. Take a piece of clean linen rag, and squeeze a small quantity of oil gold-size on to a piece of glass; then with a suitable-sized sash tool (bound round with string if the hairs are long) lay a coat of oil thinly over the surface: the thinner it is spread the better it will be for gilding; in fact, it must not be too thick, or the work will turn out dull when gilded, but cover the frame equally, thinly, and completely, touching every part and missing nothing. This operation is usually performed in the evening, so that it will be in a fit state to gild the next morning. When it is ready will be known by the dry tackiness of the oil.

There must not be the slightest suspicion of greasiness about it, nor yet must we allow it to get too dry, but take it in the humour and at the time. If it is not dry enough, leave it till it is, but do not leave it too long.

Before it is put up to dry (being in oil) over-night, take a piece of damp calico rag, and wipe off with care the grease from the burnishes.

In the morning our frame is examined and found to be ready for gilding. The leaf is blown from the book into the cushion, and cut up to the size and shape suitable to the part under operation. Take up the piece with the tip (which should be brushed across the head to make the gold adhere), place it lightly on the frame, and repeat till every part is covered. The gold is then carefully pressed into the ornament with a dabber of cotton-wool, and skewed or brushed over and over the frame in order to make the gold-dust that rises remedy all defects or parts by accident left uncovered. When the frame is perfect as far as it can be, brush off all superfluous dust, and the frame will shine like the surface of solid gold.

Now give the burnishes (if any gold has adhered to these take it off at once) two coats of burnish gold-size evenly laid. When dry, procure a glass of cold water and a camel's-hair pencil, and proceed to gild by floating the bead to be burnished with water, and quickly applying the strip of gold, which must be ready, on the tip. Should any defects show themselves, they must be remedied at once by another application of gold to the already wetted surface. This will be repeated until all the burnishes are covered, care being taken not to run too much water on the gilded portions of the frame.

This completes gilding in oil and burnish, and the flat inside must be seen to after the parts already gilt have been burnished.

The burnisher is made of agate stone in numerous sizes and shapes, the most convenient being curved, with a point that will fit into hollows and curves that require burnishing. A little practice will be better than a volume of description as to the method of using them; however, a few words will not be out of place on this subject.

Hold the handle firmly in the right hand, and with the left put slight pressure on the burnisher, and apply the curved part to the bead or the point to the hollow; keep it steadily upon the work, and draw backwards and forwards until a brilliant burnish is produced.

Now carefully overhaul the frame, and if any faults occur, be sure to remedy them before going any further. Then finish sizing, or ormolu size the frame all over except the burnishes, which must be religiously excluded from this operation.

The inside flat may consist of flat and hollow or flat and bevel, and may be burnished in the hollow or matt, according to taste.

Flats are double gilt, unless economy is the object. Double gilding gives solidity to the work in hand, and at the same time does away with any appearance of inequality where the leaves join.

The mitres may require rubbing down with glass-paper, the hollows or bevels stopping with putty if badly joined or damaged. When smooth, apply a coat of clay, emery-paper when dry, and apply four coats of matt gold-size; again emery-paper, and wash down with a sponge and clean water. When very nearly dry, use a piece of cloth, and briskly rub the surface until it assumes a brilliant polish. Upon this lay two coats of weak size (when cold it must not be strong enough to set), and allow to dry. Prepare to gild as before with camel's-hair mop and glass of water, keeping the gold from the hollow if it is to be burnished. When dry, wipe off the superfluous gold with a piece of soft wool. The faults will now probably be enormous, but the next coat will remedy that. Lay one coat of weak size over the gold, and two coats of burnish size in the hollow. This, when dry, must be again covered with gold, laying flat and hollow together. Again rub off with wool. Should any faults be visible, wet the place with mop, and put a small piece of gold over till all defects are made good. Burnish the hollow without slipping over the flat, and finish sizing the flat without the hollow. The frame will now be complete.

*Re-gilding.*—Old frames that require re-gilding undergo the same preparations as new work, with the exception of one or two little details.

If the frame is in good condition, make a bath of soda-water, and with a brush wash every part of the frame free from dust and grease, and wherever possible strip off the old gold without undermining the composition or whiting. When dry, stop up every crack, and proceed as with a new frame.

Should the ornament be broken away, it will have to be replaced. If small pieces only are missing, use a piece of glue, putty, or compo. applied and modelled as near to the shape as possible; if large pieces, a "squeeze" must be taken. Place a piece of compo. over the steam from a saucepan to soften, knead it up like dough with whiting, and proceed to take a squeeze from a perfect portion of the frame. First grease the part to be reproduced, then place the compo. over it, squeezing it into every part of the ornament; take it off, and put away till dry and hard. To take the required impression, grease the mould and press soft composition into it, wet the back, cover it with a piece of board, and apply pressure to force the compo. into every part; then loosen it from the mould, and it will come away with the board. When partly set, cut away the required ornament with a knife, place it on to the frame in its proper position, and back up with compo., smoothing all down in a workman-like manner.

Oak, if well selected, will make a good gilding surface to show the grain. After well glass-papering, give it two coats of methylated French polish and put in oil as described above. After gilding, finish sizing.

## MASONS' WORK.

BY MUNIO.

DAMP COURSE — FOOTINGS — VARIOUS KINDS OF WALLING — RUBBLE, BLOCKING, AND ASHLAR WALLING — POINTING — DRESSING STONES: PLAIN, CIRCULAR, SUNK, MOULDED, CIRCULAR MOULDED, AND SUNK AND MOULDED WORK.

*Damp Course.*—As soon as walls are brought up to the surface of the ground, a damp-proof course should be laid on, to prevent damp arising in the walls; this may be of asphalte, about ½ in. thick, laid on hot, or it may be a course of slates bedded in Portland cement, with the joints overlapping each other. A damp-proof course of glazed stoneware is also sometimes used; this is made about 3 in. thick, with perforations through it, and also acts as a ventilator under wooden floors; the damp course should be thoroughly set before being built upon.

*Footings.*—Footings are large stones laid in the foundations of walls. They should, when possible, be in one stone, and should be at least 3 in. wider on each side than the wall which comes upon them; they are from 3 in. to 6 in. thick, and are pick- or hammer-dressed. They should be bedded down perfectly solid; sometimes two courses of footings are used, the lower course projecting at least 3 in. on each side beyond the upper course. When they cannot be got the full width in one stone, they may be laid as shown in Fig. 30; when they are laid in two courses, they may be bonded as shown in Fig. 31.

*Various Kinds of Walling.*—There are many different kinds of walling, but they may be briefly summed under three heads—viz., Rubble or Random Walling; Blocking, or Block and Course; and Ashlar Walling.

*Rubble Walling.*—In this walling the stones are not made to any particular size, but are roughly bedded, and the sharp angles knocked off with the hammer in walling; a thin stone is laid under the tail of the stone, called a "pinner," and the stone hammered down on the mortar; the pinner gives the beds of the stones a slight inclination outwards, which prevents the wet running into the wall. In the Lake District, where rag walling is used, this inclination is made much greater, and the stones are said to be "watershot;" this is to prevent the heavy rains from beating through the wall; for the same reason the mortar in these walls is kept back from the face of the wall, giving it the appearance of being built without mortar, as, if built in the ordinary way, the mortar would be washed out.

A sufficient number of throughs or bond-stones should be inserted in the wall—about one in every 6 ft. of area; and those in one course should be laid between those in the course below. The bond-stones should not be left projecting out of the walls, as they are liable to be broken in cutting off the ends. Fig. 32 shows rubble walling; the large stones at the angles are called "quoins," and are generally hammer-dressed. Fence walls for fields are built in dry rubble, or without mortar, except a row of bond-stones laid in mortar in the centre of the wall; and the coping, formed of stones set on edge, is laid in mortar. These walls are built with a batter or slope on each side.

*Blocking.*—Blocking is formed of stones reduced to parallel courses. The faces are hammer-dressed, pitch-faced, or drafted and broached, the quoins being dressed in the same manner. They are walled, and throughs inserted, in the same manner as rubble walling; the inside of the wall is generally rubble work. Fig. 33 represents blocking walling. Sometimes the blockers are walled in varying courses, called "sneck walling," as shown in Fig. 34.

Some excellent blockers are obtained from the Yorkshire and Durham flag quarries; they are from 2 in. to 6 in. thick, with parallel beds; the faces are pitched; they are called "flag blockers" or "parpoints."

*Ashlar Work.*—This is formed of stones about 12 in. thick. The faces are pitched, drafted and broached, tooled, or polished; the inside of the wall is faced with rubble work or brickwork; the beds and joints are dressed with the mallet and chisel, and they are set with fine putty; bond-stones or throughs should be inserted as before named, and when openings for windows, etc., occur, every alternate stone should go through the wall; the facing-stones should also be of

varying widths, a narrow-bedded course being set on a wider-bedded course to give a better bond to the backing of the wall; the joints should be made square for at least 2 in. from the face, after which they may gradually widen out. The stones should always be set on their natural or quarry bed. Fig. 35 shows ashlar work.

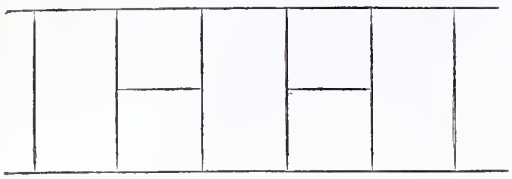

Fig. 30.

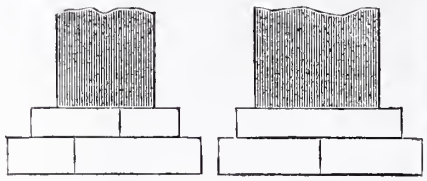

Fig. 31.

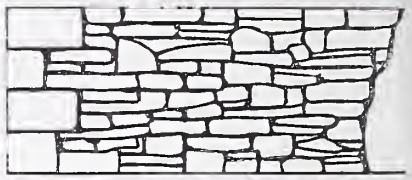

Fig. 32.

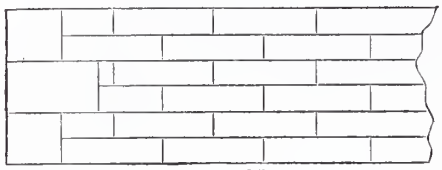

Fig. 33.

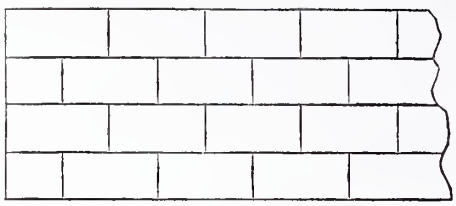

Fig. 35.

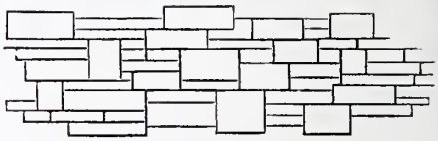

Fig. 34.

Sometimes the edges of the stones have a small chamfer formed round them, as shown in Fig. 36. This is called "Rustic" or "Rusticated Work." Sometimes the quoins only are rusticated.

Another method of finishing the face of ashlar work is called "Rock Work." This consists in sinking the face of the stone (after it has been dressed level) into various irregular forms, with a narrow flat margin between them, the sunk portion being about $\frac{3}{4}$ in. deep.

*Pointing.*—Pointing consists of filling up the joints of walling with fine mortar, to prevent rain from injuring the wall. The simplest method is called "raking off" or "dashing." In this the joints are filled with mortar, and raked level with the edge of the trowel. Sometimes a stiff brush is rubbed over it, to level the work; this is used on rubble walls.

*Lean Pointing.*—In this the joints are filled with mortar, and the trowel is drawn along to smooth it, slightly pressing the top edge inwards; the lower edge is sometimes cut off to a rule, and sometimes with the trowel-edge only. This pointing is used in blocking and rubble. Rock or pitch-faced work is pointed with a jointer with round edge; the joint is filled with mortar, and the jointer drawn along the edge of a rule. *Tuck pointing* is also used in blocking. In this the joints are filled with mortar made to the colour of the stones; this is smoothed over, and when sufficiently stiff a joint of white putty is laid on with a flat jointer by means of a rule. The filling may be made the colour of the stones by mixing it with sifted smith's ashes and stone dust till of the required colour. The putty must be well beaten, to get all the water out of it, and mixed with silver-sand and oil; the joints must be gauged to keep them parallel, and the edge of the rule is rebated to allow the putty to fall down as it is cut off; a knife with the end slightly turned up is used for cutting off the putty joint; the cross-joints are cut off with a piece of wood shaped into a set square, and a handle fixed on the face. The joints are made from $\frac{3}{16}$ in. to $\frac{1}{4}$ in. wide.

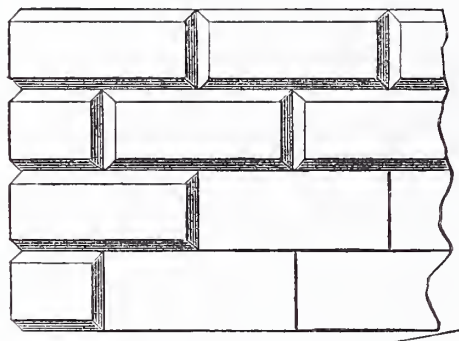

Fig. 36.

Before commencing to point a wall, the joints should be well raked out, the dust brushed off, and the wall damped, as the pointing will crack if laid on a dry, dusty wall.

Ashlar is pointed with fine putty mixed with stone dust; the joint is filled level, and the edge of the trowel drawn down the centre of the joint with a rule. Ashlar work should be washed, and the lime-stains scraped off before it is pointed.

*Dressing Stones.*—Dressing stones is the art of cutting the stones into the various forms required in building. It is designated as Plain, Circular, Sunk, Moulded, Circular Moulded, and Sunk and Moulded Work.

*Plain Work.*—Plain work consists of forming the surfaces into planes. To level the surface of a stone, a draft is run along one side and across one end with a 1 in. chisel; a rule is fixed on the cross-draft, and a draft is run across the opposite end, which must be cut so that when a second rule is laid upon it, the under edges of the two rules are

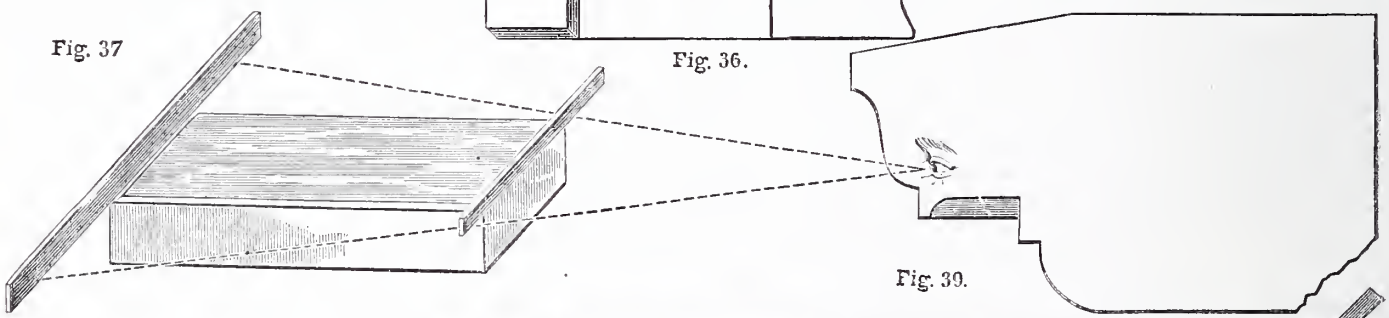

Fig. 37

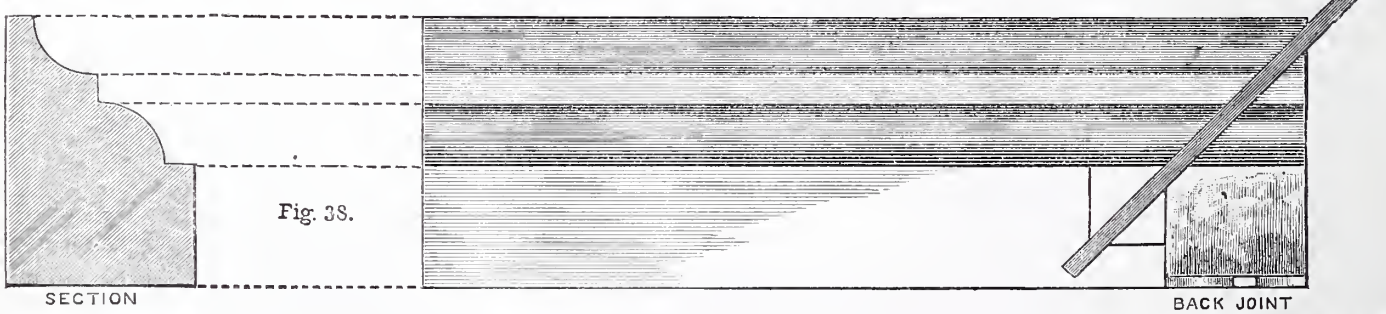

Fig. 38.

SECTION

BACK JOINT

**Fig. 30.—Footings in one Course. Fig. 31.—Footings in two Courses. Fig. 32.—Rubble Walling. Fig. 33.—Blocking Walling. Fig. 34.—Sneck Walling. Fig. 35.—Ashlar Walling. Fig. 36.—Rustic or Rusticated Work. Fig. 37.—Taking Surface of Stone out of winding. Fig. 38.—Mode of Mitring Moulded Stone. Fig. 39.—Moulded Stone with undercut Portion left unworked.**

out of "winding." (See Fig. 37.) Then divide the whole surface of the stone by drafts into spaces 10 in. square, making each draft perfectly straight; the rough stone between these drafts is levelled down with the point, and then straightened with the inch chisel; the surface is then ready for finishing. The remaining sides and ends are squared from the face already dressed. There are various methods of finishing the surfaces of stonework—Boasting, called also "Swin Chiselling" and "Droving" in Scotland. This consists in going over the whole surface of the stone with the boaster, keeping the tool-marks all one width, the sizes varying according to circumstances; but on a coarse-grained stone they are generally wider than on a fine-grained stone. Tooling consists in forming the surface into parallel lines or flutes, which are at right angles to the edge of the stone; a tool 3½ in. or 4 in. wide is used, and the strokes are commenced at the side farthest from the workman, and brought right across the stone towards him. In order to keep the tool straight, square lines are drawn at intervals across the stone. Polishing consists in rubbing the surface with a level stone, fed by sharp sand and water; the stone is rubbed with a circular movement, and care must be taken not to rub the surface into hollows: the rubbing is continued till all the tool-marks are obliterated.

Drafting and broaching consist in putting a draft round the edge of the stone, which is gauged about 1 in. wide, and struck in; the centre portion is levelled down by the point, and dotted over till perfectly level by the stone-pick or diamond-hammer.

Rock or pitch-faced work is struck off round the edges, and left with the natural face of the stone; sometimes a draft is run round the edges of the stone, and struck in parallel.

*Circular Work.*—In circular work the face or bed, as the case may be, is first reduced to a plane surface; the mould is then laid on this surface, and cut in; the remaining beds or joints are then squared from this surface. In applying the square to the joint of a circular stone, it should be held at right angles to the line of the joint.

*Sunk Work.*—In sunk work the margin of the sinking is first reduced to a plane surface; the sinking is then marked on, and cut in at each angle, using a gauge for the depth; drafts are then run between each point thus cut in, and the surface levelled to these drafts.

*Moulded Work.*—In moulded work the beds, joints, and as much of the face as is not moulded, are first reduced to plane surfaces; the mould is then marked on each joint, and cut in, and the intervening stone is then cut away, using the straight-edge for testing the work. When a return or quoin occurs in a moulded stone, it must be mitred in the following manner:—The mould is formed on one face, as already described; then work a back joint on the head end of the stone, and cut in the mould, and draw square lines from the top and bottom member, intersecting the mould already worked; and at the angle of intersection draw a square, the sides of which are 4 in. long; also draw a diagonal across the square, and lay a rule on the diagonal line, projecting to the outside of the stone; then, sighting the edge of the rule with the outside angle of the moulding, draw a line across the moulding coinciding with the edge of the rule, which will be the line of the mitre (Fig. 38); this line can also be checked by gauging. Should any part of the moulding be undercut, it must not be worked till after the return portion of the moulding has been worked, but is worked afterwards to a reverse mould; in Fig. 39 the shaded part is left till the return end is worked.

*Circular Moulded Work.*—In circular moulded work the stone is first worked to a circular form, as already described; the mould is then marked on the joints, and cut in, and the moulding is worked to circular rules, one being required for each member of the moulding.

*Sunk and Moulded Work.*—In sunk and moulded work the plain sinking is first worked at the inside of the moulding; a reverse mould is then applied, and the moulding cut in at each side, and worked by means of a rule; the mitres are formed by drawing lines, intersecting each other at the angles, from the portion already worked, and the working tested by a rule cut to an angle of 45° at the end.

## MANTEL-BOARDS: HOW TO MAKE AND FIX THEM.

BY H. HINGE.

WOOD, ETC.—WORKING AND SHAPING—DOVETAIL KEYS—COVERING, FRINGES, FANCY NAILS, ETC.—FIXING, ETC.

THESE very desirable additions to our chimney-pieces can be easily made and

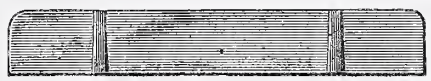

Fig. 1.

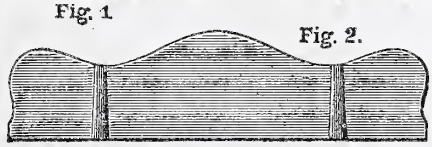

Fig. 2.

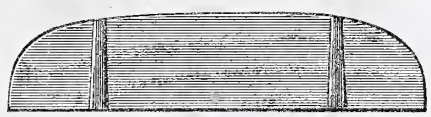

Fig. 3.

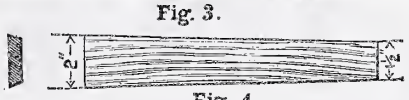

Fig. 5. Fig. 4

Fig. 1.—Plain Mantel-Board, showing Underside, for Bedroom. Fig. 2.—Shaped Mantel-Board for Sitting-Room. Fig. 3.—Alternative Mantel-Board for Sitting-Room. Fig. 4.—Enlarged View of Dovetail Key. Fig. 5.—Section of Ditto.

fixed by anyone who has a few tools and a desire to use them. The size, of course, must be ruled by the width of the chimney breast, size of room, etc., but generally, almost all chimney-pieces will admit of a mantel-board 3 in. or 4 in. longer and wider than the existing one.

*Wood, etc.*—The wood for the purpose should be good and dry. It will be easily understood that if it is not fairly dry, the heat of the fire and general dryness of the situation will cause it to split and twist, and spoil the looks of it.

*Working and Shaping.*—Procure a fair piece of deal the length and breadth required, and not less than 1 in. thick. Plane up true and straight on both sides, and then determine what shape to make it. Fig. 1 shows a board with only the corners rounded, suitable for a bedroom. Fig. 2 is the best shape for drawing- or sitting-room, and looks very well. Fig. 3, another shape, not so much used as Fig. 2. Having decided what shape to make it, measure to the centre of the board, and make a square mark across it, and then begin, and with a pencil sketch the shape you want, putting on a little or taking off (after the outline is got) until the desired shape is attained. Now cut it out with a bow saw and mark it on a paper; cut this out, and lay it on the other half, and mark it and cut it out; you will then get both sides true.

*Dovetail Keys.*—We must now put in some dovetail keys to keep the board flat and true. These are made of ⅞ in. oak or mahogany, or other hard wood, about 2 in. longer than the board is wide, 6 in. from the end. They should be about 2 in. wide at one end, and taper down to 1½ in. at the other end. Besides being tapered in the length, the edges are bevelled to form a dovetail. Fig. 4 shows a dovetail key, and Fig. 5 section of the end of key. These are to be fitted tight into the mantel-board. The best way to fit these will be to get and place them the narrow end and narrowest side down in the place we want them to come, and then mark with a sharp pencil along the edges of the key. These should be cut with a sharp saw on the bevel to match the shape of the key to a depth of ½ in., and cut out with a chisel, care being taken that the groove is of a uniform depth right through. Now see how the key fits, and if it has been done right, it will just drive in tight. If it is too tight, plane a little off the edges of the key; but be sure it fills nicely, or it is of no use. When both keys are fitted, they should be marked about ¼ in. shorter at each end than the board is wide, carefully driven out again, and then cut off to the marks with a saw. They should only be glued about 1½ in. at the narrow end (which comes to the front of the shelf). The glue is best put in the groove, so that when the key is put in no other part will get glued except the end. These are now planed off level with the board, and, if done right, will admit of the board shrinking without splitting or becoming unlevel. In a long board put in three keys, one at each end and one in the centre. Take off all sharp edges after the shaping is finished.

*Covering, Fringes, Fancy Nails, etc.*—Cover with crimson or green cloth, or any other colour harmonising with the surroundings. This is easily done by tacking the material to the back edge of the board first, and bringing it over the top side, and just pointing in a few tacks to keep it in position, and slitting the cloth anywhere out of sight to facilitate it fitting the shaping, and pulling it down, taking out the tacks that were pointed in as we go along, and pulling it tight and tacking it on the underside of the board. If carefully done, it will present a nice level surface, and fit the shaping, and leave no wrinkles anywhere. If a fringe is going on to the front edge, it should be backed by a piece of the same material as the shelf is covered with, about 2 in. narrower than the fringe. This is tacked along the front edge, not pulling it tight anywhere. If we do, it will be pinched at the corners, and not fall nicely. The fringe is put on in the same way, turning a little under at the ends to prevent it roving. It must now be finished along the front edge with fancy brass nails put in at equal distances of about 2 in. or 3 in. This is best done by setting out with a pair of compasses. It will be found that the brass nails all require boring for with a fine sprig-bit, as they will bend and be disfigured if they require much driving in. Macramé work makes very good and durable fringes.

*Fixing, etc.*—Our mantel-board is now

finished in itself, and only requires fixing. If the chimney-piece it is going on is wood, there is no difficulty; it simply wants screwing down from the underside. If it is iron or marble, we shall want two rebated pieces of wood to clip the underside of mantel-shelf, and screw to the underside of the board. These can be made by screwing two pieces of wood together, one the thickness of the shelf, and allowing the other piece to stand over about ¾ in., and then screwing right through both pieces into the shelf at the right distance from each end, so as to clip the bottom shelf. If fixed in this manner, it can be taken off at any time to clean, etc., by simply sliding it off.

## A USEFUL HAT OR CLOTHES STAND.

BY T. S.

Many readers of Work have changed their residence some time or another, and, on changing, have doubtless found that the old cornice poles, which had been well suited to the old house, were either too large or too small for the windows of the new residence, and thus have been led to put them away in the loft, and buy new poles. It occurred to me that a good stand could be made from one. This I have made, and hope the description will be useful to others. I had a piece of a good mahogany pole cut off a long one when I last moved, with the knobs at end, and I made a three-legged stand for it, screwed on some brass hooks that were also the result of a "move," and I find it

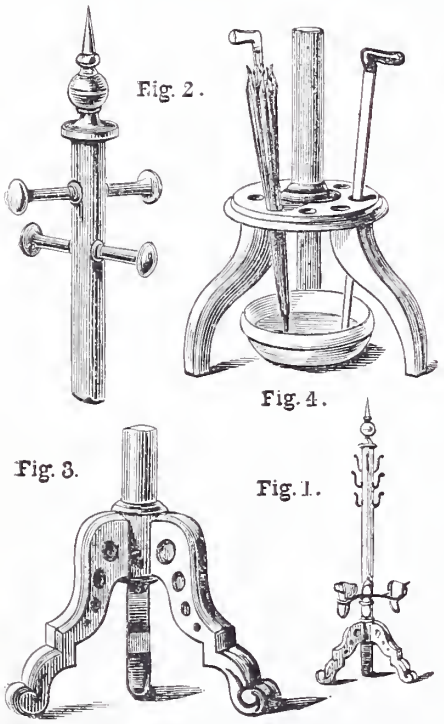

**Fig. 1.—Sketch of Hat or Clothes Stand complete. Fig. 2.—Enlarged View of Top with Pegs. Fig. 3.—Enlarged View of Bottom or Foot. Fig. 4.—Adaptation of Bottom for Sticks, Umbrellas, etc.**

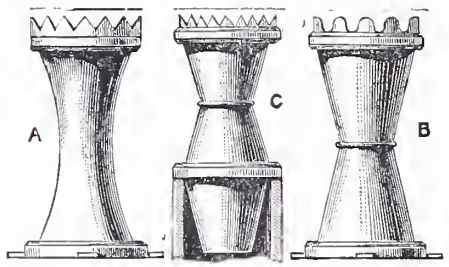
most useful. It stands in a corner, and my clothes hang on it when I am in bed, instead of across the foot of the bed. Thus they get nicely aired, and are put on with pleasure in the morning. This stand also avoids disfiguring the door of bedroom with hooks, and could be made to stand in the corner of a landing or hall, where any other stand could not be placed. Mine is 4 ft. 6 in. high, and has a foot like a three-claw table or music-stool; but if a rather longer pole is used, the three claws could be screwed to side of pole, and the lower end of pole stand on the ground, or be finished with a knob, like the top. The claws could be cut and shaped out of stuff from 1 in. to 2 in. thick, taking for a pattern any table or music-stool you can get at. A reed or moulding could be scratched on the edges, holes sunk in the sides by a large centre-bit, etc. Fix to the pole by one screw through the top part of leg, and one through the pole between two opposite legs. If you have a lathe, you may turn the pins and the base; but if not, brass hooks, or even black iron hooks, would do. The feet should be about 18 in. apart to get a good base, or the stand will be top-heavy. The lower part could be made with holes to take boots or slippers. The top knob takes the hat.

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of Work for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of Work without charge, the notices given partake in no way of the nature of advertisements.*

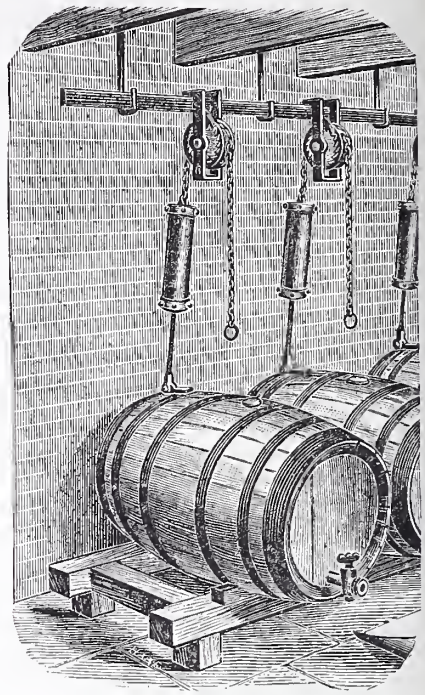
### 41.—Mitchell & Hare's Improved Pot or Cowl.

In the summer, when the fires are over and the chimneys swept, and ready for the winter when it



**Mitchell & Hare's Improved Pot or Cowl—A, B, Ordinary Cowls; C, Cowl for Stove.**

comes round again, persons who are troubled with chimneys that smoke will be taking the necessary precautions to prevent, if possible, a recurrence of the nuisance. In the next number of Work an expert, who writes under the *nom de plume* of "Excelsior," will show us how he manages to do this by judicious alterations of the throat of the chimney just above the grate or fireplace; and in this number, Messrs. Mitchell & Hare, Bedale, Yorkshire, or 10, Chesson Road, West Kensington, show us how it may be prevented by placing a suitable pot or cowl at the chimney top. The form of "The Comfort," the improved pot or cowl by which this desirable result is attained, is shown in the accompanying illustration, in which three shapes are shown, of which two, A and B, are intended for placing on ordinary chimneys; and C, for stoves. The principle of the invention consists, as may be seen, in making the pot narrower in the middle, either concave, as in A, or tapering, as in B and C, and wider at both top and bottom. This, Messrs. Mitchell & Hare say, tends to prevent down draught and the ill-effects arising from it, as the contracted or narrow part acts as means whereby the force of the downward draught becomes broken and gradually expended, and the up draught improved. The manufacturers consider B to be the best shape. They send me a copy of a letter from Messrs. Garlick & Horton, Limited, Builders and Decorators, 43, Sloane Street, London, S.W., to this effect:—"We have much pleasure in informing you that we have fixed your 'Patent Comfort Cowls' to a number of houses in this neighbourhood, and found them a success in preventing down draughts in some very bad flues, and shall be glad to recommend them." The price of "The Comfort" Cowl in galvanised iron is 21s.; and in earthenware or pot, 15s. and 10s. 6d.



**Thomas's Patent Cask Tilter.**

### 42.—Thomas & Sons' Patent Cask Tilter.

When a cask of ale or beer is getting low, it often happens that the liquid remaining in the cask is seriously impaired and rendered "muddy" by shaking up the dregs in tilting it. To obviate this, Messrs. Thomas & Sons, Acme Hoist Works, Cardiff, make and supply a patent cask tilter, known as "Walker's Patent Cask Tilting Apparatus," which appears to form an improved and handy appliance for automatically tilting barrels and casks without disturbing or shaking up their contents. It is said to be light, portable, and simple in construction, and such as can be easily and quickly fixed. Its principle is apparent from the accompanying illustration, in which it is shown attached to the first, second, and third of a goodly row of barrels in a capacious cellar. First of all, hooks are attached to the joists, in order to give support to a rod of iron, on which as many cask tilters are hooked as there may be barrels. The portion of the apparatus hooked on to the bar consists of an iron frame carrying a ratchet wheel and a pawl, which engages in the teeth of the wheel as it revolves, and prevents its return in the opposite direction. Over the wheel passes a chain, free at one end, and attached at the other to a cylindrical case, in which is a spring. At the lower end of the case is a hook of special form, by means of which a firm and instantaneous grip is obtained on the rim of the cask when the hook is attached to it. To set the Cask Tilter, the hook is fixed to the rim of the barrel, and the chain is pulled until the spring inside the Cask Tilter, as the cylindrical case is called, is compressed flat. The apparatus is then ready for work. As the liquid is withdrawn, the spring gradually returns to its normal position, and, in doing so, tilts up the end of the barrel without the slightest shock until it is empty. When empty, the pawl is released by pulling a string attached to it, and the cask immediately runs back to its original position. The price of the Cask Tilter, which is said to be suitable for barrels and casks containing any quantity up to a hundred gallons, is 17s.

The Editor.

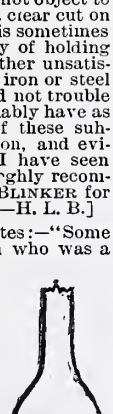
### I.—Letters from Correspondents.

**Gilding on Glass.** — Blinker writes:—"I fear that Young Signwriter will not find H. L. B.'s instructions (No. 112, present Vol.) in every point satisfactory. By his use of the terms 'inside' and 'outside,' H. L. B. would seem to have a *window* in his mind (an excellent thing, by-the-bye, facilitating enlightenment). Now it is obvious that our young friend will never be able to paint a clear, sharp letter on a vertical surface (rather a mixed expression that; but never mind) with a size so thin and fluid as is used in this process. Even were his glass laid flat, its evenness would offer irresistible temptations to the size to indulge in frisky little excursions on all sides. I have never seen the thing attempted in this way, and, having a horror of bad language, I never want to. Let Young Signwriter lay on his size—which is not expensive, for the spirits of wine may he dispensed with—liherally, and when it has drained to a thin film, cover all that part of his glass wbere lettering occurs with leaves of gold neatly laid to overlap each other the 'laste taste in life.' This must now drain and dry, dryness being indicated hy the disappearance of the minute irregularities which make the gold look 'mat' and the reappearance of burnish. While this process is going forward, Young Signwriter cuts a stencil or stencils (hints have appeared in Work), which will cover the gold that is to *remain* on the glass, and expose the *superfluous* to the action of a stiff but not harsh brush, as a nail-brush. The stencils may be made in stout paper of hard texture (continuous roll preferred), and as they are not to be roughly used, they will serve a number of times, though thin stencil metal will be better. Young Signwriter need not be told that it is practically impossible to *paint* a letter so clear, sharp, and altogether lovely, as can be produced by stencilling of this kind, even though he used a much more workable size than this, which is hardly more than water; and if he has a number of tablets to be lettered, or any kind of repeating to do, the advantage of stencilling—not to say the absurdity of using any other method—will at once be apparent. If he is engaged on plain lettering which lies between two (imaginary) right lines, *one* stencil, to remove gold from *between* letters, will be sufficient, and superfluous gold from tops and bottoms can be cut away with—a match-stick, for instance; care being taken to lay the straight-edge across slips of wood, to prevent contact with gold-film, which is easily damaged. Shading may now be painted in, if required, and the whole backed up any colour. I should have mentioned that stencils are not laid upon a board during the process of cutting, but upon a piece of glass—*not* the piece heing decorated, of course, but a waste piece which does not object to being scratched. You cannot ohtain a clear cut on any yielding or uneven surface. Lead is sometimes used for this purpose, but it has a way of holding the point of your knife, and is altogether unsatisfactory. Zinc is better, and polished iron or steel is almost as good as glass; hut I need not trouble to say so, as our young friend will probably have as easy access to the latter as to any of these substitutes."—[This is valuable information, and evidently written by a practical man. I have seen work done in this way, and can thoroughly recommend the process. I am obliged to Blinker for kindly supplementing my instructions.—H. L. B.]

**Spanner.** — W. E. (*Liverpool*) writes:—"Some time ago I was working with a man who was a good engineer. He came to put some 1 in. steam piping, and had forgotten to fetch his pipe tongs. He said he was not much concerned about them, he could screw up round piping with a square spanner, which he did, and made a good job of it. He got a spanner a little bigger than the pipe, and inserted a bit of a rat-tail file between the pipe and jaw of the spanner, which held the pipe, I think, better than tongs would. I enclose a rough sketch—A is a bit of rat-tail file; B shows the pipe."



Spanner.

**Bicycle Parts.**—Messrs. W. A. Lloyd & Co. (*Birmingham*) write:—"We have been inundated recently with applications from amateurs for our price list, and we find it is largely owing to the article appearing in your journal of May 30th, on 'The Construction of the Safety Bicycle,' in which our name is mentioned as one of the firms where parts, etc., may he obtained. We shall be very glad if you can find space in the next issuc of your valuahle paper to say that we can only supply the *actual 'cycle trade'* with fittings; and if any of your readers require our goods, they can he obtained from any cycle agent in the country. We may say it is evident your paper must have an enormous circulation, as the applications have heen very numerous indeed, and have come from all parts of the kingdom."

### II.—Questions Answered by Editor and Staff.

**Celluloid on Piano Keys.**—Leicester.—Take the keys off the frame. Now get a level board to lay your keys on, then glue two strips of hrown paper on the two top edges of the hoard; then put a spot of glue on the underside of the key hack and front, and glue to the strips of paper, placing them in their natural position, leaving the sharps out. Having taken the old ivory off, tooth the tops of the keys. Now tooth your celluloid well, and saturate the side you have toothed with methylated spirits. This softens it. When the spirit has evaporated, you are ready to glue with ordinary glue. I should advise you to lay it in four pieces. You will require a caul made hot. Now glue carefully, and press with handscrews and leave to dry. You will find that you can easily separate it from the paper; then turn over, and cut apart with a fine saw. Where the sharps fit in, cut with saw across, then with a knife from underside cut the piece out, finish with file, and polish with bath-hrick and paraffin or spirits and whiting, and plenty of friction.—T. E.

**Sticker Action.**—Repairer. —The action you speak of is what is known as the "Sticker Action." Remove the stickers from the levers, and take the hinges from the butts; number with pencil each one, so that they go baek in the same place. Pull the old hinges out of groove with a pair of pliers. To re-hinge, ohtain fawn-skin sticker hinge (it is 1 in. wide), bend in middle, and strike with a hammer, holding it on a piece of iron, and form a hinge smooth side out. Cut into lengths sufficient for six, glue the groove, and press leather in with a piece of thin steel; a stay-husk makes a usc-ful tool for this purpose. You may re-cover levers with fawn-skin cut to the width you require, and glue on top first and allow to dry; then pull tight round and glue on the underside, and hold in position with hammer springs. Now slack the screws in the hammer rail, and take out the centre wire with the butts on. Take off the butts, and remove old bushing. Ohtain a set of bushing eloth and point the ends, and glue and allow to dry. This makes a point to thread with. Now thread the cloth in the butt, leaving a small portion hanging out. Glue this, or use shoemakers' paste, and draw level with side of butt, and cut with knife; when dry, broach for centre wire. If you now put the centre wire in, and fix the hammers in the rail, you can re-cover them. Remove the felt by cutting across the front of the hammer with a sharp knife (only cutting the outer covering), and tear off. Ohtain a strip of felt, and after tapering the edges down with a knife, cut the felt across a shade wider than the hammer-head. Glue the top side first, and put a spring on each, and allow to dry; then pull felt firmly over, and glue underside; fasten with spring and allow to dry, when you can trim the sides. Do not glue the front of the hammer. Use a shoemaker's knife, and sharpen on emery-cloth. If you do not cut the sides of hammers very nice at first, press between two warm flat-irons. Obtain a strip of damper felt, and cut to the width you require, and glue on, holding with a spring until dry. To put new vellum in levers or dampers, saw slightly across just behind hinge, and open with a knife; take out old vellum, and having prepared your vellum by gluing hoth sides and allowing to dry, place in the groove, damp the wood, and hold a warm iron on it. This will soften the glue on the vellum. Now put spring on, and allow to dry. You may now put your stickers in their place. Lay the action down on your bench, and glue the bottom of sticker and hinge at one time. Put the bottom on the lever, and hinge on the hutt, and with a sticker hook press the leather on the hutt front and back. After stickers are dry, ease them backwards and forwards—not too much, only what is necessary when in the piano. The materials for repairing action you can ohtain from Hallpike, 213A, Mare Street, Hackney, London; the tools from G. Buck, 242, Tottenham Court Road. Ask for pianoforte maker's spccial price list.—T. E.

**Cost of Copper Sheets.**—Anxious.—I find that a sheet of copper ¼ in. in thickness, and 4 ft. long hy 2 ft. wide, weighs ahout 36 lbs. As there are eight square feet in a sheet of this size, it therefore follows that the weight per foot super. is 4½ lhs. The retail price of copper, varying, according to the market, from 1s. to 1s. 3d. per lb., you would find very expensive to use, a sheet of the size stated above costing ahout 35s.; though, if you are in the metal trade, or could get anyone in the trade to get it for you, there would, of course, be a good discount off retail price.—R. A.

**Tinners' Mixture.**—F. H. (*Birmingham*).—I am not aware of the existence of the mixture you ask about for darkening the colour of tin. If, as you say, it is a tinners' secret, you may depend upon it that it is only to bc got by paying for. As you appear to have the opportunity of seeing it used, could you not get hold of a little, and submit it to analysis? or if it is of value to you, as I suppose it is, ask the users of the mixture their terms for imparting the secret.—R. A.

**Scenic Artist.**—Work.—Consult the *Era*, theatrical newspaper. You will find scenic artists and assistants are advertised for weekly. Also study my instructions in Work.—W. C.

**Plating Safeties.**—F. C. (*Manchester*). — The materials required to nickel-plate two safeties are a floating bath, a battery, nickel, ammonia, hi-sulphite of soda, and the practieal experience of a nickel-plater. The process of plating, you will see, is entirely different from painting black enamel. It is not a painting process, hut a dipping and depositing operation hy the action of an electric battery. Nickel-plating may, however, be done without a hattery, hut it would not be advisahle for a novice to try even it. The process is as follows:—A porcelain or copper vessel, large enough to dip a handle-har, is required. Into the vessel is placed a concentrated solution of zinc chloride, diluted with one and a half its volume of water, and heated to hoiling. As much powdered zinc as will lie on a shilling is then thrown in, which will coat the interior of the vessel with zinc. The nickel salt, which may he the chloride or sulphate of nickel, is now added until the bath appears green. Now put in some zinc fragments and the articles to be plated, and hoil for fifteen minutes. When taken out, wash with clean water, and clean with chalk or jeweller's rouge. If you want a thicker coating, repeat the process.—A. S. P.

**Plating.**—J. C. (*Wraxall*).—You seem to imagine that nickel-plating is put on with a brush, like paint, whereas it is a process of dipping in a bath charged with nickel, ammonia, etc., under the action of a hattery, so that an outfit for nickel-plating one's bicycle is out of the question. Send it out to a professional plater, who will do it for about 10s.—A. S. P.

**Size.**—Hawk.—I have never used Cognet's patent powdered size, therefore do not know its properties. If you cannot get the ordinary jelly size, and you find the results not satisfactory, get 1 lb. of hest treacle, ½ lh. hest yellow soap, and, say, 1 lh. of your powdered size; bring it all to a boil, but do not let it hoil. These ingredients should be put into 3 quarts of water before placing on the fire. When all is ready, pour this into your soaked whiting, well mixing it. Let it get cold. When cold, it is ready for application. The room being cold and damp would not make much difference, hut, I should say, rather depressing for any artistic work.—W. C.

**Cost.**—Working Man.—I should roughly estimate the cost of such a building as you have described to be worth ahout 5½d. a foot cube to huild. The way you can arrive at the amount is as follows:—Multiply the extreme length of building by the extreme width, and the total by the height half-way up the roof, thus:

| | | |
|---|---|---|
| Length of building ... ... | 36 ft. | |
| Width of building ... ... | 38 ft. | |
| | 288 | |
| | 108 | |
| Superficial arca of building ... | 1,368 ft. | |
| Height of building ... ... | 12 ft. | |
| Cuhical contents of building ... | 16,416 ft. | |
| Price per foot cube ... ... | 5½d. | |
| | 82,080 | |
| | 8,208 | |
| | 12)90,288 | |
| | 20)7,524 | |
| Cost of building ... ... ... | £376 4s. | |

You omit to state the proposed height of building, so I have taken it at 12 ft.—that is, half-way up the roof. In addition to the ahove, it would cost about 1⅘s. a yard to have the hall tiled. You must distinctly understand that this is, as you suggest, only a rough guess, as you have furnished me with no particulars heyond saying that the situation proposed is four miles from a hrick-field, and the little omission I have mentioned above.—E. D.

**Transfers, etc.**—Engineer. —You can ohtain gold transfers from Mr. H. M. Stevenson, 6, Edmund Street, Birmingham, or Mr. W. Gay, 115, Holloway Head, Birmingham. To draw water from the river that runs by your works by means of a lathe seems to me a rather curious proceeding; hut if you wish to do it, get a small rotary action pump from Messrs. Warner & Co., Creseent Foundry, Cripplegate, London, and work it from the slow motion of your lathe hy means of a gut-line or shaft. The third question on your paper—How to utilise the river for driving purposes—could only he satisfactorily answered hy an experienced millwright or engineer viewing the place, and taking all the circumstances of the case into consideration. The data that you give—that the stream is ahout 10 ft. wide, and runs very swiftly—is not sufficient to form any idea of the place, and space in "Shop" is too valuable to waste in mere conjecture. I should think, from the general tone of your letter, that a perusal of some elementary works on mechanics and hydraulics would he beneficial to you.—R. A.

**Marbling.** — A Plasterer. — Your letter and drawing give me no idea of the purpose you propose utilising the pedestal for. If it is to be used as a stand in a living room, then it will look best

finished in one plain general colour. It would certainly be a mistake to paint it in imitation of many kinds of marble; the finished effect, especially in the hands of a novice at marbling, would be common and poor in the extreme. I would not, personally, advocate trying to imitate any one kind of marble, save those of a quite general colour. With such an object, wherein the structural ornamentation is a special feature of its value, the veining of marble would detract from the effect of the enrichment, and would destroy much of its delicate form. Assuming it to be a room pedestal, I should paint and enamel it either alabaster colour or as black marble, and enrich it by gilding the caps and cornice blocks solid with gold-leaf. This would look good and rich, and not "cheap and painty." —DECORATOR.

**Greenhouse Wash.**—B. A. W. (*Croydon*).—Prepare a mixture of white lead paint, made from white lead 1 lb., patent driers 1 oz., and thinned to desired consistency with four parts turpentine to not more than one part raw linseed oil. This must be barely and evenly painted with an ordinary paint-brush upon the outside of glass, and then finished to look like obscured or ground glass by stippling—dabbing—evenly over with either a pad of flannel, soft carpet, or the tips of a larger new dry paint-brush. This paint will not wash off with rain, but you will find that by the time the heat of a summer's sun has been spent on it that it can be removed without much labour, by damping it over and rubbing with a piece of soda, taking care not to have sufficient moisture on the glass to run down and "eat off" the paint from the woodwork. —F. P.

**Varnish.**—J. T. (*Nottingham*).—Copal oil varnishes are of a more durable nature than polish or varnish prepared from lac and spirits. In the former case, the oil combines with the copal gum to make a film which gets harder with age, whilst the lac has not such aid in spirit varnishes from the vehicle in which it is dissolved. Notwithstanding the foregoing, *any* copal varnish would not suit your purpose, since warmth from handling the rods would probably make them slightly sticky. The most durable and quick hardening covering I could suggest is a white enamel varnish or Bath varnish. Such a preparation is rather expensive, but it has all the advantages of durability given by copal varnish, combined with the quick hardening nature of a spirit and lac mixture. You could not profitably make this. Mander Bros., of Wolverhampton, is the firm you should apply to.—F. P.

**Graining Tools.**—DECORATOR.—If you want to purchase in any quantities for retailing, etc., write either Messrs. Crowden & Garrod, 62, Southwark Street, London, S.E.; T. Pavitt & Sons, 70, Southampton Row, London, W.C.; or J. Hill, 230, Pentonville Road, London, N. In buying brushes, be willing to pay a fair price; "cheap and good" seldom go together in this respect. If you require a book of practical value to supplement the series of papers on sign writing which appeared in WORK, Vol. I., get the "Art and Craft of Sign Writing," from 15, St. Ann Street, Manchester. It is the most complete work published, containing everything appertaining to the subject, coloured and gilded samples, etc. The price is 21s.—F. P.

**Patent Leather Boot Varnish.**—OLD SUBSCRIBER.—When patent leather is first taken into wear, its brightness may be preserved by well dusting and rubbing with a soft cloth, and then applying a little white of egg with the finger. This being such a fine transparent layer, it seldom wants washing off; but should the leather want cleaning to receive any other preparation, it can be easily removed with a little warm water. A good varnish that will wash off can be made by boiling ½ oz. of logwood chips in ½ pint of soft water, and adding a piece of copperas about the size of a filbert nut. Strain off the chips, and add to the liquid 1 oz. of gelatine, ½ oz. of isinglass, 1 oz. of sugar, ½ oz. of glycerine, and 1 gill of common port (ale will do). Boil gently, and well stir till all are dissolved; strain again through fine muslin, and when cold it is ready for use. It should be about the thickness of double cream. Another good and simple dressing for patent leather is—one of linseed oil to two of best cream. Just warm it on a slow fire while you mix it well together. Apply with a piece of sponge, and when dry, rub with a soft cloth till you get a brilliant polish.—W. G.

**Lithographing.** — LITHO. — There is no paper published which is devoted exclusively to lithography, but there are several which deal with lithography in connection with printing, publishing, and other branches of the trade; such as the *Lithographer*, the *Printing Times and Lithographer*, the *British and Colonial Printer and Stationer*, the *British Printer*, etc. I should recommend the *Printing Times and Lithographer* (published at 73, Ludgate Hill, E.C.) and the *British and Colonial Printer and Stationer* (published at 58, Shoe Lane, E.C.); the former being a monthly paper, and the latter a weekly one.—A. J. A.

**Cooking Stove.**—T. P. (*Weston-super-Mare*).—I have not any information on the subject of the curious cooking stove described in your cutting from *Cassell's Saturday Journal*. I scarcely think (ingenious though the device is) that it will, as the writer says, revolutionise the art of cooking. With regard to a good paraffin cooking stove, Rippingille's will bear favourable comparison with any other maker. I have used them myself, and frequently have to overhaul and repair them, so can speak from experience. For cleanliness and convenience, especially in summer time, these stoves are very useful indeed. I think your friend must have neglected his stove for it to have worn so badly; with proper care, they will last for two or three years without repairing. The following directions may perhaps be of service to users of oil stoves. Fill the tank up every day of using, whether there is any oil left in or not. Carefully wipe all spilt oil off the tank before lighting; avoid, if possible, the boiling over of saucepans, etc., placed on the top. If they do happen to boil over, see that the stove is wiped dry after it is done with. If put away out of use for a time, empty the oil, take out the wicks, and keep in a dry place. By these means the stove will last as long again.—R. A.

**Spangled Tin Goods.**—A. H. K. (*Birmingham*).—I am unable to give you the process by which this is done, as I do not think it is generally known. You would most likely be able to obtain the material from the Tin-Plate Decorative Co., Neath. —R. A.

**Moderator Lamps.**—W. M. (*Market Drayton*).—You can get your lamp repaired at Benham & Froud's, Chandos Street, London, W.C., or Gardner's, Charing Cross; and there used to be some years ago a shop in Gerrard Street, Soho, W.C., whose proprietor dealt specially in lamps of this kind, but I cannot say if it is still in existence. Your lamp, when in good condition, and if it is a full-size one, ought to run at least four hours with once winding. —R. A.

**Dead Black.** — BRASSWORK. — The best thing that I can recommend you for a dead black is something that I have been using lately myself for my camera and lens tubes. It is called "Enameloid," sold in shilling bottles by the Frederick Crane Chemical Company, 22, Newhall Hill, Birmingham. It is a perfect dead black, absolutely non-reflective, and will bear any handling. Berlin black is also a very good black, but not so dead a surface as enameloid.—R. A.

**Piano Sound-Board.** — PERSEVERANCE. — The sound-board must be planed all over, not merely at the edges. You can obtain a sound-board (ready to put in, with the exception of the bars and bridges) from R. Peace, Blackstock Road, Finsbury Park, London.—T. E.

**Rust on Wrest-Pins.**—F. S. M. (*Huddersfield*). —Having cleaned the rust off, get some good Brunswick black, and with a camel-hair brush paint each pin and allow to dry. You can clean the bolts with emery-cloth, but you will probably take the blue off. If you wish to blue again, take one out at a time, and hold in the flame of a gas-jet near the head until it turns blue, or you may black them.—T. E.

**Cox's Glue.**—G. A. (*Liverpool*).—Write to the agents, Fordham & Co., York Road, King's Cross, London, N.W., when they will probably inform you where to obtain it in your town, or send you the quantity you require.—T. E.

**Piano Matters.**—AMBI-DEXTER.—I should make your bracings 4 × 3. From your letter I judge you would succeed. With regard to your other question, £6 would cover cost.—T. E.

**Tuning Hammer.**—The hole is drilled in before it is tempered, the top of the shank is square where it is inserted in the handle, and a washer riveted on the top; the handle is simply turned out of hard wood. You can purchase one for 5s. 6d. from Buck, Tottenham Court Road, London.—T. E.

**Piano Matters.** — PUZZLED. — I presume you have made the strings too wide apart for the hammer-head to strike them. With a flat punch knock the pin a little closer, and if there is a deep impression, re-cover. As you have put more strain on your piano, you will have to strengthen it by gluing some half-inch hard wood up each side of the bracings as far as wrest-plank.—T. E.

**Fretwork Patterns for Piano.**—F. S (*London, W.*).—Write to H. J. Fletcher, 161, City Road, London, E.C.—T. E.

**Piano Keys.**—LOWERBY.—If your keys are made of ivory, rub with No. 1 glass-paper, then polish with a flannel pad damped with methylated spirits and whiting.—T. E.

**Fairy Bells to Piano.**—J. H. C. (*Edmonton*).—You must tune to the natural notes of a piano if you can get access to one. It is a simple matter to tune them to each note. Make the shortest string to the pitch or middle C on the piano, then follow each white key towards the bass, and tune each one following, when your longest string will be two octaves below pitch C. You can purchase a few wrest-pins or pegs at any pianoforte dealer's.—T. E.

**Piano Wrest-Plank.**—J. C. (*Bolton*).—To take out piano wrest-plank, lay the piano on its back, and take a slip of wood and fit in at the bottom edge of the plank, and mark very carefully with a pencil where every string crosses. This makes a scale, as your hammers must all strike the strings when your new plank is in. Now take a sheet of paper the size of the plank, and with a piece of heelball rub over the paper when laid on the bridge, so that you get your bridge in the right place. Now take off your strings, and bolts out, then take off the wood on top and chop out; make the new one exactly the same, and, if possible, take the bridge off whole to use again.—T. E.

**Looking-Glass Frame.**—BARRA.—If the frame is a plain moulded one, without enrichments or carvings, you would have little difficulty in staining and polishing it black, as you wish. If perfectly plain, the gilt surface could be easily removed, or at least reduced, by rubbing with some fine glass-paper, taking care in so doing not to round off all square members or sharp edges; if there are carvings, you might use a little methylated spirits with a rather stiff brush, such as a sash tool, but do not use water unless you allow it to thoroughly dry, as polish or varnish will not take kindly to anything damp. Having prepared the groundwork, mix some vegetable black in one part polish, or varnish, and three parts methylated spirits; give several applications till you have a dull, even surface; then polish, using white polish and a little gas, or Frankfort black, in your rubber, or mixed with your polish, and finish with glaze, or varnish, or spirit-ing out, as may suit you best. Failing your ability to French polish, I am afraid you will have to fall back on the process you seem to object to, and use some black enamel; but of this there are several brands in the market, one of which, known as "Foo-chow," being made of spirit instead of oil varnish, ought to suit your purpose capitally. It does not give that thick bright surface you object to, and it can, by thinning down with methylated spirits, be made to give an almost dull appearance. You will not, of course, without using extreme care, be able to save untouched all the parts you require gilt; it will be better to do all over as suggested, then cut in the parts or any design you may require gilt with a little oil gold-size, procurable at most oil and colour merchants, to which, when nearly dry, you can apply gold-leaf, Dutch metal, or bronze. You will find full directions for gilding in Vol. II., pages 718 and 750. As regards the treatment of plain wood, instead of that faced with whiting, you do not say what kind of wood it is—whether polished or not; if the former, and a black ground is required, the foregoing treatment will suit; if the latter, the wood will require staining first: this can be done by means of a logwood stain, though it is cheaper and more cleanly to use French black stain, procurable at most places where veneers are sold, and colour merchants; or you might use the Improved Ebony French Polish, as sold by T. Jackson, 199, Borough High Street, London, S.E. This is a stain and polish combined. Should you require other colours than black, and wish to show the figure of the wood, you will have to stain by means of one of the many recipes to be found in "Shop," and finish by polishing.—LIFE-BOAT.

**Iron Lasts.**—A. T. H. (*Acton Green*).—You say "pack"—but of course you mean fit up—"iron lasts for pegged and rivcted boots." Well, for the former an iron last is of no use, but a wood last must be used, for, in making pegged work, the peg-awl must go through the whole of the materials, and a little way into the last. This is that the peg may go just through, that it may be rubbed down inside; hence the use of the peg-rasp and peg-knife. Were you to use an iron last, you would blunt the peg-awl each time you made a hole, and the peg would not go through, and solidity could not be the result. Iron lasts are just the thing for the latter, as the rivets are clenched as they reach the last. They are fitted up according to their particular construction. If they are ordinary block lasts, and you want to fix a joint or long-leather on them, it can easily be done by fixing these with a waxend to the block before putting the block on the last. Of course they must be fitted and blocked to their shape on the last first. Or another, and the best, way, is to take the last to an iron-foundry, and have holes drilled where you want fittings to be put on. You can fill the holes up with gutta-percha or wood, and then nail the fittings on the lasts. The way to sharpen a shoemaker's buff-knife is to run it through a piece of tallow, and lay it flat on a board with the edge you want to sharpen flush with the edge of the board on the right-hand side; hold the knife on firmly with the left hand, by pressing all four fingers upon it, and with the stem of a sewing-awl, stiletto, or steel burnisher, rub down the edge backwards and forwards; this will throw a fine burr right across the edge. Turn it over, and repeat this process on the other side. This done, hold the knife, edge upwards, in the left hand; place the right thumb against one of the side edges, and draw the awl from the centre to the corner, letting the awl run on both the burrs at the same time, and keep stroking it till the edge is flat. This will throw the burrs over on to the sides again, but they will have a keen and even edge, for each time it is sharpened, it throws over a little more steel. This second process has to be repeated on the other half. Do not let other tools come in contact with it; keep it by itself.—W. G.

**Crayon Drawing.**—W. W. C. (*Kelso*).—A rapid and showy method of shading is by first "stumping" in the shadows, and then hatching over them with the chalk point. The stump, I may explain, is a little roll of wash-leather, cut to a conical point, which is dipped in powdered chalk and worked over the paper. "Hatching" is drawing a series of lines which cross each other, but they ought not to cross at right angles. This, however, is not the method in favour in the Government Schools of Art, or in the Antique School of the Royal Academy. In these schools it is the practice first to go over the shadows with very rough hatching —scribbling it might rather be called—and then to work and "stipple" over and between the lines with the chalk point, taking out any harsh line or touch with bread-crumb. This plan gives greater delicacy, and enables the student to render such shadows as he sees before him far more accurately and conscientiously than the first-named

method. For serious study, its advantages can scarcely be questioned. W. W. C. should, if he can, see a School of Art, or get a lesson or two from one of the students. He would thus learn much more about the matter than from columns of description. As to tools, all that he needs will be his port-crayon, a few French chalks, and a penny loaf.—S. W.

**Piano Repairs.**—W. R. W. (*Poplar*).—You can obtain new hammers for your piano from Hallpike, 213A, Mare Street, Hackney, London (probable cost, 10s.), and wire from Hughes, 37, Drury Lane (probable cost, 25s.). Apply to Rudd & Co., 74, Dean Street, Soho Square, for an estimate.—T. E.

**Piano Wood.**—MUSICUS.—Formerly oak was used for piano wrest-plank, and if you veneer it well to prevent splitting, I see no objection to your using it.—T. E.

**Square Piano.**—H. A. C. (*Plaistow*).—Any stationer will give you the information about binding WORK. There are only sixty notes on your piano, but you have confused notes with strings. There are two strings to each note, except perhaps at the extreme bass, where there are a few single strings. When you string your piano, count notes, not strings.—T. E.

**Piano Label.**—S. H. B. (*Barnstaple*).—It is a very simple matter to put label or name on fall of piano. You can either use polish or glaze. Scrape the old label off with a chisel carefully, then level with glass-paper, rub a little glaze or polish on the back of label, and put it in its place. See that the air is pressed out with a soft rag, and leave to dry. Then give it a rubber of polish in the ordinary way.—T. E.

**Piano Making.**—CRESCENDO.—Yellow pine will not make a good sound-board, as it is too soft, and makes the tone without ring in it. A better substitute for Swiss pine would be good quality spruce, free from knots. You could obtain a sound-board ready jointed from R. Peace, Blaekstock Road, Finsbury Park, London (cost about 5s., carriage and packing extra). The bottom plate is made of iron ⅛ in. thick, and is bolted on the bottom of piano; the holes are drilled in the top edge and pins placed in. I should advise you to buy one ready made. Covered strings, 11s. to 12s.; steel wire, 1s. 9d. per lb.; wrest-pins, 2s.; bridge-pins, 1s.; bent side and bottom plate, 3s. 6d.; keys and action, £3.—T. E.

**Felt on Piano Hammers.**—NOVICE.—Kindly see reply to G. T. (*Chatham*) on page 61, No. 108, Vol. III., of WORK. Felt may be obtained from Hallpike, 213a, Mare Street, Haekney, London.—T. E.

**Fairy Bells.**—F. (*Preston*).—I thought I had made the instructions clear. It says distinctly: "Over the bridges you will find sizes of wire and number of notes in brackets. There are four strings of No. 8, four strings of No. 9, four strings of No. 10, and three strings of No. 11, all steel music wire."—T. E.

**Fretwork.**—H. S. C. (*Manchester*).—Get the Indexes to Vols. I. and II. of WORK, and you will find fretwork hints and designs and cupboards by the score.

**Bicycle Parts.**—SUBSCRIBER.—All parts for cycle making are obtainable of—Brown Bros., 7, Great Eastern Street, London; W. A. Lloyd, Lionel Street, Birmingham; Thomas Smith & Sons, Saltley, Birmingham.—A. S. P.

**Ticket Writing.**—WUERDLE.—For materials, paints, brushes, etc., apply to Messrs. Brodie & Middleton, Long Acre, London, W.C.

**Worm and Wheel.**—LETTER CUTTER.—I do not think you can buy a worm and wheel such as you require, and will have to get them made. You did not say what pitch the teeth would have to be, but as the spindle of the worm-whool is only ⅜ in., I may suppose they will be fine, and the worm only of the ordinary ¾ in. Whitworth screw rate. There must be many a workman in Aberdeen who could make you a worm and wheel such as you describe, and I think 15s. should cover the cost.—F. A. M.

**Water Motor.**—A. J. (*No Address*).—You ask what pressure is required in the mains to give you one horse-power. That depends on how much you use. You might as well ask what pressure you must have in a steam boiler to give you 10 h.-p. You might have a pressure of 5 lbs. and get 10 h.-p. in one engine; or you might have 100 lbs. per square in. in another, and yet get no more. In some mains you may have one or two hundred lbs. per square inch, and a small quantity of water at that pressure will give you considerable power; so, too, you may have a slow stream of water, having only a few inches of fall, and yet, if there be plenty of water, you may get the same power. See my remarks on page 23, middle column, of the present volume, and do not think of drawing one horse-power from the town mains; it may cost you five shillings per hour. It is all very well for those who have a natural fall of water.—F. A. M.

**Piano Defects.**—L. C. (*London*).—I should judge that the depreciation in the tone is not caused by the small cracks (which denote that the wood has not been dry), but by the sound-board having sunk, so that the strings do not bear sufficiently on the bridges. Take out the back, and wedge three or four bottle-corks tightly between the upright bracings and the sound-board. This may improve it if the sound-board is firm. The action you have sent a sketch of is known as the "Costa." Probably the felt on the hammer rest is hard; if so, place a piece of flannel over it, and try. Does the hammer-head touch the wire that raises the damper? Noises can only be detected by patient listening to find the cause. If the hammer does not strike with sufficient force, turn the wire which is under the arm that is prominent to the left; if it does not free itself from the string, turn to the right.—T. E.

**Blow-Lamp.**—WATER-PIPE and E. D. (*No Address.*)—A very good lamp for the uses you wish to employ it for is the French methylated spirit blow-lamp, Fig. 1. If you really wish to try and make one, you cannot do better than get an old police lantern; this will give you a start with the body if you take the glass out, and cut front to the shape shown in the sketch; the lamp also could be brought in with a little alteration. The top chamber, C, is the part that you would have most trouble with; it is, as shown in sketch, spherical in form, with a screw on the top for filling; there is usually a valve in this screw, but I will tell you how to dispense with that. The simplest way to get over the difficulty is to make a vessel as near the shape as you can, and this you can easily do (see Fig. 2, which illustrates the following description):—Take a strip

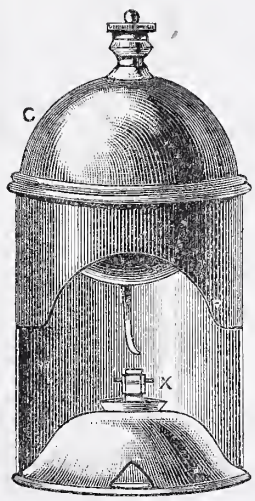


Fig. 1.

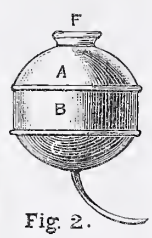

Fig. 2.

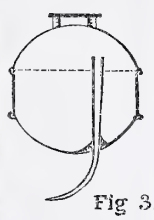

Fig 3.

**Fig. 1.—Blow-Lamp. Fig. 2.—Home-Made Reservoir, equivalent to C, Fig. 1. Fig. 3.—Section of Reservoir, showing Position of Blow-Pipe.**

of copper or brass, whichever you please, ¾ in. in width, and long enough to go round the inside of the lamp body; let it fit fairly tight, and give a ½ in. lap and soldor it; this will form the centre piece B. Next cut a circular piece, ⅝ in. larger in diameter than the piece just made, hollow this up, slip it *inside* the piece B, then cut another circular piece for the top A; as this ought to be hollowed up more, cut a little larger than the piece C, and this piece must he "capped" on to the piece B, as it will then form a ledge, and prevent its slipping down the lamp body. Before soldering, a hole must be punched in the A piece for the filling screw F, which should be a good one, and have either a leather washer or a ground in stopper, such as is used in the best class hot-water bottles. A small hole must also be made in the C piece for the blow-pipe to pass through. Fig. 3, which is a sketch of the reservoir, shows how the pipe is situated; it must be some distance out of the centre, and should come up inside to within ⅛ in. of the top, so as to allow the reservoir to be somewhat over half full to start with. Solder this pipe round well inside, fix the filling screw, and then solder the top and bottom. The blow-pipe may be the end of one of the ordinary gas-fitter's brass blow-pipes, costing about 6d. The lamp itself should have a single tube ⅛ in. or 3/16 in. in diameter; the wick should be the same as used in ordinary bull's-eye lanterns, viz., that sold in large balls; it is a soft, loose, twisted wiek, and should not he packed in too tightly. The flame may be regulated to some extent by the same means that was adopted in the benzoline lamps when they first came up—that is, by an outside tube made to slip firmly, yet easily, over the wick tube (see X, Fig. 1). To use the lamp, fill the vessol C, Fig. 1, about three parts full, or, in other words, not quite up to the level of the inner tube (see dotted line, Fig. 3), with methylated spirit, and the lamp with the same; light the lamp, and as the spirit in the top vessel gets hot, it throws off a gas, or vapour of spirit, which, blowing on the flame of the lamp, forces a strong jet of flame of intense heat outward. Should the lamp not commence to blow in a minute or two after lighting, blow it out, and run a small wire up the blow-pipe to clear it; by being careful about this a valve on the top may be dispensed with. I think that for most purposes that a blow-lamp is required this home-made affair will answer well, but, of course, you cannot expect to do brazing with it. I have not made any experiments to try if this lamp will work with benzoline in place of methylated spirit, but I should think that very likely it would.—R. A.

**Dampness.**—W. N. B. (*Glasgow*).—The only remedy is a dry area, a description of which you will find on page 461, No. 29, Vol. I. Do not, under any consideration, waste your money in rendering the inside of the walls with Portland cement, for although it is very good in some instances, it would be of no service in yours. The ground being so very much higher at the back of house than the front, it is most probably above the damp-proof course; and if it is so, you will find it impossible to keep out the damp whilst the ground touches the wall above the floor and the damp course, and your only remedy is as above. We will now take it for granted that you have constructed a dry area wide enough for a man to work in comfortably right round the external walls of the room you complain of, and still the room is damp (after having allowed a sufficient time for the room to dry—say, three months); and from the fact of the ground under the floor having been asphalted, I should not be very much surprised. You can take it for granted that the damp course is defective, or that the stone facing of the wall is very porous, and absorbs the driving rain and other moisture. You should now from the dry area carefully inspect the damp course (if one exists), and see if you notice anything wrong with it; and, if so, remedy it. If there is not one, and you still wish your room to be drier than it is after constructing a dry area, you must put one; but this job requires rather a lengthy description. If, as far as you can see, the damp course is all right, insert three or four air-bricks along each wall. If you consider the external stone-work to he porous, you had better render it with Portland cement and clean-washed sand, in the proportions of three of cement to one of sand, 1 in. thick, and trowel the face down very fine and smooth, and do not leave it from the float. A very good plan would be to cover the external faces with slates or other waterproof material, hut whatever you do must be done from the outside, for that is where the defect is.—E. D.

**Green Stain.**—A. H. W. (*Newcastle*).—The usual medium for staining green the fancy artistic furniture to which you refer is made by mixing verdigris with hot vinegar; but I find the aniline dyes known as Tomlinson's, sold in one penny and threepenny packets, equally as good; in fact, I prefer the latter, owing to the facilities for getting various shades. For instance, if the green is too bright, it is easy to add a little of the blue or black dye. Both can be finished by the usual process of French polishing, using white or transparent polish and varnish. If "filling in" is used, it is, of course, coloured to match by adding some green pigment, such as emerald or Brunswick green.—LIFEBOAT.

**Stencils.**—J. W. (*Shobdon*).—Your experience with regard to the suitability of "bought" stencils for any special purpose is a common one. The rubbing of stencil border you enclosed is a *motif* not original to myself. The combination of rose, shamroek, and thistle worked into an acanthus scroll, is carved as a frieze to a wing of Buckingham Palace, built by one of the "Georges," and I have repeatedly soen it worked as a steneil scroll border. The one you send is fairly well drawn, and does credit to your experienee, showing that you have grasped the idea of practical fitness in the arrangement of the ornament for stencil cutting.—LONDON DECORATOR.

**Lantern Slides.**—T. A. G. (*Stratford, E.*).—Transparent black lines or shadows, and clear glass in the high lights, such as you ask how to produce, are signs of a perfect lantern slide, and most amateurs find this their greatest difficulty. First, as to the best process. There is no doubt that the finest results can be obtained by the old wet-plate process. This is used by some of the largest and best makers, and has the additional advantage, where a quantity is wanted, of being the cheapest; but if you are an amateur, making only a few for your own use, the dry-plate method or the carbon would be far better. The latter is not very often employed, but when successfully done, very beautiful effects can be obtained; directions for this, unless asked for, would be too long for the columns of "Shop." This leaves the dry-plate process the one most favoured by general workers. The plates are best bought ready prepared, and there is little to choose between those of the best makers. They are all slower than ordinary plates, and I would advise you to use those made by the same firm as you patronise for negatives, except you wish for warm tones, and the only ones in the market I know of which will give these are the Ilford "Alpha" lantern plates. I eannot make sure, from your letter, if you ask for best devoloper and exposure for various subjects, or only for making slides of hymns; there would be a difference, the latter having no half-tones, only black and white. For this work use a slow plato, rieh in silver, for the negative, and do not over-expose it: if anything, the other way; and if you are familiar with the quinol developer, use that; if not, a pretty strong pyro. Develop well out, getting plenty of density. For the lantern slide about the same treatment, and either quinol or iron developer (not pyro. for this).—W. E. D., JR.

**Coloured Picture.**—F. C. (*Clacton-on-Sea*).—The specimen you send is a coloured print mounted in contact with the glass, made transparent, and backed with plaster of Paris to give it greater brilliancy. You would not find the process difficult. To obtain like results, get a print (the one sent is printed in colours, not coloured afterwards), then make some good strong starch, such as is used for mounting

photographs; coat the print with this, and rub down upon the glass. Scrape out as much paste as you can by going over the back with a piece of hard wood cut thin at the edge, something like a turning chisel or the end of a paper-knife, working from the middle to the edges. The more carefully this part is done, the better the article will look when finished. Let it dry, then sand-paper as much of the paper back off as possible, taking care not to make a hole; brush over with paraffin wax to make it transparent, and if a concave glass, like specimen, fill up with plaster of Paris, or you can back with white paper. You would, I think, find photographs mounted in the same way look much better than prints, and for local views would be easier to obtain. Use those that are printed rather deeply; they could then be coloured on the back with oil colours after being made transparent, and finished off with white paper backing; or if not coloured, they need only be cemented to the glass.—W. E. D., JR.

**Banjo Vellum.**—C. E. (*London*).—There is no necessity to sew your vellum when putting it on. If your band is a piece of thin brass, I should advise you to take it off and fit a new one. Banjos having only a thin piece of brass for a band are never a success. When the top of band is pulled down level with the vellum, the points of brackets are almost sure to cut into it, and, of course, break it. Get a piece of brass long enough to go round hoop, ½ in. wide and about ⅛ in. thick, bend it round to shape, halve ends for lapping over one another, then braze them together, or drill two holes and rivet them. Put the band on hoop, and mark exactly where each bracket comes, then file out notches to sink the nose of brackets in, so that they are clear of vellum. Use a piece of brass or galvanised wire to go inside of vellum and under band. In putting on vellum, have it at least 2 in. larger in diameter than size of hoop; or, better still, have it 3 in.—it will be all the easier to put on. With a bradawl make a series of holes round the edge of vellum, keeping them about ¼ in. from the extreme edge, and about 1½ in. apart. Take a piece of banjo string, second or third, and long enough to go round edge of vellum, and thread it through the holes, taking care that both ends of the string come out on the underside. Put the vellum in water to make it pliable; do not let it stop in too long—say, about one minute. Let the water drain off. Lay the vellum on hoop, put on the brass wire ring, and pull the ends of string, turning up edge of vellum all round. Pull the string tight, and see the edge of vellum lays well over; tie the string, and then put on the band that pulls the vellum tight. Put on six or eight brackets at equal distances apart, then pull down band evenly all round. It will be better to use longer screws, made specially for the purpose. Let the band stand up above the level of hoop, say, about ¼ in., until the vellum is thoroughly dry before pulling down further; if you let it stand a couple of days you will be on the safe side, the part of vellum under band taking longer to dry than the exposed part. Put on all the brackets, then cut off edge of vellum near top of band, so that there will be no fear of its slipping when pulled down. When dry, it must be pulled down evenly and gradually, a little at a time, until the band is level with the edge of hoop. Your vellum ought then to be very tight; if it is not, keep on pulling down until it is. Of course, the string is taken off vellum after the band is on.—J. G. W.

## III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Chair Seats.**—W. J. B. (*Deptford*) writes:—"I want some chair seats. I have tried those that are sold at oil-shops, but I find they don't last long, being composed of three pieces of very thin wood pressed together. What I want is something similar, but all in one piece—say, ¼ in. thick. Please say what kind of wood would be most suitable."

**Battery.**—T. R. (*Ashton-le-Willows*) writes:—"Will some reader inform me if there is a battery that will work for six months without being attended to? It is wanted to make contact every second—half-second in contact and half-second off. Current from two Leclanché cells will be as strong as would be required."

**Fret-Wood.**—B. C. E. (*Birmingham*) writes:—"Would any reader kindly tell me the best place in Birmingham to get fret-wood, and what is the price per foot?"

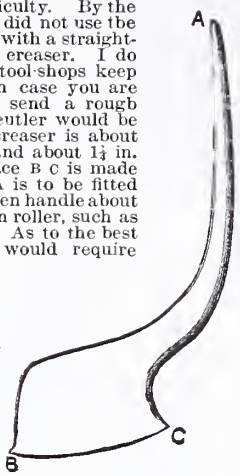
**Riddle.**—W. H. (*Pendleton*) writes:—"Will any reader kindly give me a design for a riddle for a chaff-cutter? Also information as to how it is worked?"

**Melting Brass.**—H. B. (*East Hartlepool*) writes:—"Will any reader kindly give me a design, dimensions, and instructions how to make a small furnace to melt about 12 lbs. of brass in a crucible? I want the furnace to be made on the portable principle, so that I can take it to pieces or put it together in a very short time. I want the same to be kept in the back yard, to be used to make brass ornaments."

**Compasses.**—J. W. E. (*South Darenth*) will be obliged to any reader who will furnish him with a design for a pair of 6 in. steel compasses, with a short note as to making the same.

## IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Checkering.**—A. T. B. (*No Address*) writes, in reply to CHECKERED (see page 142, Vol. III.):—"To begin with, the tools you will require are—(1) a checkering-board, which should be made of dry wood, planed up true and square, and of any convenient size, say, 24 in. long by 14 in. wide by ½ in. thick. A piece of millboard glued on to each side will give a harder surface to work upon, and prevents warping, but the side used for checkering must be quite flat and smooth. (2) A checkering-rule. This is simply a parallel rule on a large scale, which should be at least as long as the board, and a little narrower. One of the long arms of the rule is fixed to the board near the edge, leaving the other arm to work freely. A cabinet-maker would make the board and rule. I do not know the cost, as I never bought one, but have made my own. I should think you might do the same without much difficulty. By the way, the old checkerers did not use the parallel rule, but worked with a straight-edge instead. (3) Steel creaser. I do not know whether the tool-shops keep this tool in stock, but in case you are not able to get one, I send a rough sketch, from which a cutler would be able to make it. The creaser is about 6 in. long from C to A, and about 1¾ in. long from C to B; the face B C is made very smooth; the end A is to be fitted firmly into a strong wooden handle about 10 in. long. (4) A wooden roller, such as an ordinary rolling-pin. As to the best means to checker, it would require considerable space to describe the process fully, and it varies somewhat with different workers. A short time with a checkerer would probably do more than pages of letterpress, but perhaps the following hints may be of some use. Before being checkered, the leather is damped with clean water, stretched more or less, rolled (on a piece of polished marble or other suitable substance), and left till nearly dry. Place the checkering-board on a bench or table of convenient height, raising the board slightly, so that it may slant towards the worker; draw out the rule as far as it will go, and place under it the leather, so that a small corner extends beyond the rule and at the required angle; then the creaser, which has been previously heated (the degree of heat is learnt by experience), is held in the right hand at the lower end of the handle, while the upper end rests against the right shoulder. At the same time, the rule is held firmly by the thumb and the first and second fingers of the left hand, the third and fourth fingers resting on the board. To make the stroke, the creaser is placed close to the rule, the face B C on the edge of the leather nearest the worker, and the right shoulder is moved rapidly forwards and backwards, driving the creaser across the leather. As soon as the stroke is made, the rule is moved the required distance without raising the left hand from the board; another stroke is made in the same way, and so on till the leather is covered. It is then turned to the opposite corner, so as to form a check, and the operation is repeated. I strongly advise you not to make your maiden attempt at checkering with anything valuable, but procure instead some waste pieces of leather, and work upon them until some confidence is acquired in the use of the tools."



Steel Creaser.

**Cotton Belting.**—A. R. (*Scorrier*) writes, in reply to S. A. & Co. (*Stockport*) (see page 158, Vol. III.):—"To prevent injury to the edges of your cotton belts, sew strips of leather the whole length of your belts, letting the leather project a little beyond the edges of the belt, so as to take the friction. Cotton belts can be had with strips of leather fastened with copper wire by means of a machine."

**Camera.**—M. (*Bishop Auckland*) writes, in reply to BOY SORTER (see page 206, Vol. III.):—"(1) You can buy a ½-plate camera, lens, and stand, from Messrs. Lancaster & Son, Colmore Row, Birmingham, for 21s.; and having had a little experience as an amateur photographer, I would not recommend you to get one at a lower price. If you make any progress, you will soon want a larger camera. You had better send for Messrs. Lancaster's catalogue (price 4d.), which gives prices and descriptions of a great many different kinds. If you find any difficulty in selecting what you want, if you write again I shall be glad to give any other information. (2) 'Photography for Amateurs,' price 1s., Cassell & Co. (3) The Ilford dry-plates are very good."

## V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—T. L. (*Risecholm*); ROUND O; H. B. (*Sheffield*); T. W. P. (*Ilkley*); TROOPER; LITTLE JIM; G. W. O. (*Durham*); NEVER-SAY-DIE; S. C. T. (*Knutton*); A NEW SUBSCRIBER; W. L. (*Brunteliffe*); J. H. (*Bacup*); W. W. (*London, E.*); G. F. C. (*Southampton*); J. **Victor** Cycle Co., Grimsby, sell Mail Cart Wheels. [3 R

**Who's Lunt?**—Why, the Best Man for Joiners' Tools, of warranted quality. Send stamp for our Seventh Edition Reduced Price List.—LUNT, Tool Merchant, 297, Hackney Road, London, E. [9 R

**The Universal Amateur Exchange.**—Electrical, Optical, Mechanical, Chemical, Photographic, etc. Established 1862. Catalogues, 2d.—A. CAPLATZI, Chenies Street, Bedford Square. [5 R

**Turning Classes or Turning Lessons.**—Those who would be willing to conduct evening classes; also those who can give instruction at their own house, are requested to forward their address, stating which they can undertake. —BRITANNIA CO., Colchester. Technical schools and workshops fitted up complete with tools, engines, shafting, etc. [6 R

**Lettering and Sign-Writing made Easy.**—Also full-size diagrams for marking out eight alphabets, only 1s. — F. COULTHARD, Darlington Street, Bath. Note.—100 Decorators' Stencils (60 large sheets), 2s. 6d.

**Fret, Carving, and Repousse Patterns.**—100 of either, full-size, 1s.; 300 Turning Designs, 1s.; 400 small Stencils, 1s.; 500 Shields, Monograms, &c., 1s., post-age free.—F. COULTHARD, Darlington Street, Bath (late Bournemouth). [1 S

**Fretwork and Carving.**—Catalogue, with 1,500 engravings, Sixpence.—ZILLES & Co., Wilson Street, Finsbury, London. [8 R

**Joiners' Tool List,** post free.—BOOTH BROTHERS, Tool Makers, Dublin. [10 R

**Cricket Bargains.**—Must Sell. Four splendid all-cane-handled match bats, thoroughly seasoned, and good driving blades, worth 13s. each, price 6s. 6d. each; two match balls, 3s. 9d. each; pair leather leg-guards, 5s.; pair white canvas ditto, 6s.; pair wicket gloves, 3s. 6d.; better pair, 5s. 6d.; 2 pairs batting gloves, 4s. 6d. pair; set of ash stumps, 4s. 6d.; and handsome guinea bag, 10s. All perfectly new and good, and would be sent on approval before purchase. — Address, "CRICKET," Bloemfontein House, Shepherd's Bush, London. [2 S

# A WONDERFUL MEDICINE.

# BEECHAM'S PILLS

Are universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, and all Nervous and Trembling Sensations, &c. &c. The first dose will give relief in twenty minutes. This is no fiction, for they have done it in countless cases. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

**Worth a Guinea a Box.**

FOR FEMALES THESE PILLS ARE

"A priceless boon, a treasure more than wealth; the banisher of pain, the key to health."

These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the nervous and debilitated is,

***BEECHAM'S PILLS have the Largest Sale of any Patent Medicine in the World.***

Prepared only by the Proprietor, T. BEECHAM, St. Helen's, Lancashire, in Boxes 9½d., 1s. 1½d., and 2s. 9d. each. Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

# FRETWORK FOR AMATEURS OF BOTH SEXES AND ALL AGES.

Eclipse Design, No. 102.

Wall Bracket. Price 5d.

THE MOST PROFITABLE AND FASCINATING OF ALL HOME PASTIMES. EASILY LEARNT.

J. H. SKINNER & Co. having *Dissolved Partnership*, are offering their *Enormous Stock*, including 250,000 FRETWORK PATTERNS and 100,000 ft. of Solid and Three-Ply FRETWOOD, Veneers, &c.; 1,000 Gross of FRETSAWS, besides an immense quantity of TOOLS, OUTFITS, &c., as a special inducement to their customers to order at once.

**4,500 1s. Books of Fretwork Patterns**, each containing Twelve Large Sheets, beautifully lithographed, none of which would be sold retail at less than 2d., and many at 3d. and 4d. each; also

**1,200 2s. 6d. Books of Fretwork Patterns**, containing Twenty Sheets, 19 in. × 12 in., of new designs, many of which would retail at 6d. each. These Books,

**£375 in Value, will be GIVEN AWAY.**

Amateur customers ordering 5s. worth of designs from Catalogue will be presented with one of the above 1s. Books. Those ordering 10s. worth will receive a 2s. 6d. Book.

**An Allowance of 10 per Cent.** *in goods* will be made on all mixed orders for Wood, small Tools, Saw Blades, and Designs, amounting to 10s., and **15 per Cent.** on orders amounting to 20s. and upwards. NOTE.—*This reduction does not apply to Treadle Machines.*

N.B.—A SPLENDID OPPORTUNITY FOR BEGINNERS.

**Complete Fretwork Outfit**, comprising 12-inch Steel Frame, Forty-eight Saws, Awl, File, Four Designs (with sufficient Planed Wood and 1s. Handbook on Fretwork). **An Archimedian Drill**, with brass handle and Three Bits, will be **SENT GRATIS** with each Set. Post free for 3s. 6d. Outfits on Card, 1s. 6d. and 2s. 9d., post free. 6 ft. 2nd quality assorted planed Fretwood, 1s. 9d.; post free, 2s. 6d. 12 ft. ditto, ditto, 3s.; post free, 4s. 3d.

**SKATES!!!**—EVERY PAIR WARRANTED.—Sizes, 7½ in. to 12 in. No. 1, Unpolished Beech, 10d. per pair. No. 2, Polished Beech, 1s. 6d. per pair. No. 5, "Acme" pattern, all steel, 3s. per pair. No. 7A, "Caledonia" pattern, self-adjusting, one screw fastening the whole skate, the best principle, 6s. per pair. No. 8, Metal frame, with strap complete, 1s. 9d. per pair; postage, 5d. per pair. These are not rubbish; we warrant every pair.

NEW CATALOGUES of Machines, Designs, Wood, Tools, etc., with 600 Illustrations and full instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. A Specimen 6d. Fretwork Design SENT GRATIS with each Catalogue; also a List of Designs, Outfits, Tool Chests, etc., at Greatly Reduced Prices to clear.

N.B.—All orders *must* be accompanied by remittance. APPLY—

# Little Folks for JULY forms *the commencement of a New Volume,* and the first instalment of a New Story by L. T. MEADE, entitled "Four on an Island," and the opening chapters of a New Tale, called "To School and Away," by H. ATTERIDGE, are given. Among the more noticeable features of the Part may be mentioned No. 1 of the "Tee-to-Tum Tales," by LUCY FARMER; "Queer Musical Instruments"; "Stories of the Unexpected," by E. M. WATERWORTH; and a chatty article under the heading of "From Over the Sea," describing the changes a nugget of gold undergoes before it appears in the form of a half-sovereign or a sovereign. "Climbing the Falcons' Crag," "Carried off by an Ape," "Stop Thief!" and "George Weston's Adventure" comprise a few of the Complete Stories; while "The Mermaid and the Lobster" is the title of a humorous poem illustrated by GORDON BROWNE. MAGGIE SYMINGTON contributes another of her "Sunday Afternoon Chats," and a Special Prize Competition is arranged in which readers in all parts of the world can take part. Besides the above features, there are a number of Short Stories, "The Editor's Pocket-Book," Anecdotes, Poems, "Pages for Very Little Folk," Puzzles, Music, etc., and the Part is profusely illustrated, including a Frontispiece in Several Colours. [Price 6d.]

Fig. 4.—Shape for Canes of Cot. Fig. 5.—Laying on Cords (A); a Solomon's Knot (B); a Macramè Knot-Stitch (C). Fig. 6.—Solomon's Knotted Bars and Network below Second Cane. Fig. 7.—Bars fastened to Cane to form Bottom of Cot.

## HOW TO MAKE A SWING-BASSINETTE.

BY CHARLES E. DODSLEY.

ADVANTAGES OF SWING-BASSINETTE—PRINCIPAL POINTS IN FRAMEWORK—PIECES AND THEIR DIMENSIONS—STYLE OF OUTLINE—JOINTS—MORTISES—TENONS—PUTTING FRAME TOGETHER—CASTORS—HOOKS—CANES FOR FRAMEWORK OF COT—MATERIAL FOR COT—ITS COLOUR—MACRAMÈ CORD FOR NETTING—SOLOMON'S KNOTS AND KNOTTED BAR—ATTACHMENT OF CORDS TO CANES—FORMATION OF BOTTOM OF BASSINETTE.

FOR the benefit of those who read this paper having present or prospective requirement for an article of domestic furniture such as is herein described, I will, before directing how a swing-bassinette may be made, give what I consider the great advantages it possesses over the old-style cradle. One dictionary meaning of cradle is, a bed which may be rocked. A short experience of the same unpleasant rolling motion would develop in many the nauseating sensations attendant upon an attack of *mal-de-mer*, yet the poor helpless babe is made to undergo daily experiences of this kind—a mild form of churning. How different the soothing movement of a hammock! Who that has enjoyed it can forget the pleasant swaying to and fro beneath the leafy branches, the sunlight glinting between the leaves, and the faintest south wind stirring them to a whisper, lulling gently into a happy state of *dolce far niente?*

Such advantages as the following will be evident on glancing at the illustration (Fig. 1). The cot is raised to a convenient height above the floor, thus keeping the little occupant out of draughts; and if other children are about they cannot get to baby without leave, and so many a cry may be saved, consequent upon excessive loving. There is no chance of tumbling over it. It is much more handy for the mother, requiring no stooping to attend to baby during the day, and stands conveniently at the bedside at night. It is supported on castors, and so may be easily moved wherever desired. Lastly, our swing-bassinette is superior to a metal one, being strong, but light, warmer, and much less in cost. It may be elaborately finished, according as the worker's taste may dictate and pocket allow. You will notice two distinct kinds of work are entailed in the making: the supporting frame, in wood, and the bassinette, or cot, of knotted macramè thread upon a cane foundation, lined and padded, forming as comfortably easy a snuggery for the "cannie wee bairnie" as the fondest parent could desire.

The two principal points requiring thought in designing the framework are (1) that it shall with ease bear all the strain of leverage upon the posts, and so obviate all fear of collapse; (2) that it cannot be easily overturned. As the whole weight of the cot and occupant depends from the top of one post, and at an equal height from the other, there is considerable inward pressure of the posts. This inward leverage is modified by means of the short spurs, the weight being thrown more into the centre of connecting-bars, relieving the joints from over-strain, and so danger of collapse is avoided. The possibility of being overturned is secured against by the length of the foot-rests or steps, and position of spurs.

Now, to work. I do not think anything will look better for the wooden frame than oak, either polished or plain. Pieces of the following dimensions will be required:—

Head-post—4 ft. 5 in. by 1½ in. by 1½ in.
Foot-post—3 ft. by 1½ in. by 1½ in.
Two connecting-bars—each 3 ft. 2½ in. by 1 in. by 1 in.
Three rails—each 6 in. by 1 in. by 1 in.
Four spurs—each 1 ft. 2½ in. by 1 in. by 1 in.
Two spurs—each 6½ in. by 1 in. by 1 in.
Two foot-rests—each 1 ft. 7½ in. by 1½ in. by 1 in.
Curtain-rail—1 ft. 1 in. by 1 in. by 1 in.

It will be seen that the style of outline is square and octagonal. This, however, may be varied at the will and ability of the worker, the posts, etc., being turned or carved to any design; but I think the method of fitting and jointing I have adopted is as reliable as any way. All the joints are mortise-and-tenon glued, and secured with a pin about $\frac{3}{16}$ in. thickness. The tenons are cut the full width of the wood, except the spurs and rails; the tenons at the bottom of the upright posts measure 1½ in. by 1 in. by $\frac{5}{8}$ in., a mortise being cut through the centre of each step to correspond; the tenons at the ends of connecting-bars, 1 in. by 1¼ in. by $\frac{5}{8}$ in., with mortises in the uprights to correspond, the lower bar being inserted 9 in. from the bottom of posts, above the step, the top one 5 in. above it. The rails are fixed into connecting-bars at equal distances apart—*i.e.*, 8¼ in. space between each. Cut the tenon at each end of rails ½ in. by ½ in. by ¼ in., and so leave rails 5 in. long. The spurs are fixed as shown in Fig. 2, being permanently secured by a long pin passing through the top, the upright connecting-bar, and the spur at the other side. The tenons of the spurs will be cut at an angle; if the uprights be fixed into the step, and the piece of wood to form the spur placed in position at the side, the angles at which the tenons are to be cut will be easily marked off. Fig. 3 explains itself. The short spurs are fixed at an angle of 45 degrees. The curtain-rail is 1 ft. in length, and may be round or octagonal, a knob being left at the end to prevent the curtain slipping over. This rail will only require to be glued in.

All the separate pieces being finished and ready for uniting, we may put the wooden frame together. I have simply given measurements and working outline, leaving details to the worker; for I guess no one would make a commencement who mistrusted his own ability to complete it. First, glue the rails into connecting-bars, clamp firmly into position, and set aside. Place the step flat, and the upright with spurs on either side above it, all being ready glued; with a mallet drive together, and secure with a pin through the steps. Allow time for the glue to set, and then unite the posts with connecting-bars and short spurs. Fix on the castors last; these should be small, and placed at the ends of the steps, so that the weight rests well between them. The hook in the foot-post is 2¾ in. from the top, that in the head-post being an inch higher. On the top bar, above the middle rail, fasten a narrow thong of leather or a macramè band, to act as a stop strap, leaving 5½ in. on either side, with dress-hooks at the ends. This is to prevent the cot swinging, unless desired.

So far, all has been plain work. The cot will be to many a new departure, but when finished it will fully repay for the time and patience spent over it. First will be wanted three canes, each 7½ ft. or 8 ft. long, which may be had from dealers in basket or wickerware. Bend these into shape, as shown in Fig. 4, two of them being equal in size—length 2 ft. 9 in., breadth 15 in.—and the other one of a smaller circumference, being 2 ft. 5 in. by 12 in. broad. To join the canes, taper off the ends so that they fit closely together, unite with marine glue, and rivet with two or three small wire nails, boring a hole first to prevent the cane splitting; then bind with thin twine. For the handles, two pieces of cane, each 8 in. long, will be needed. Taper off the ends and fix on to the top cane, uniting and securing the same way as above. As the elaboration of design in the woodwork is left to the worker's taste, so the choice of colour and material for the cot must be. Fawn-coloured cord, with lining of peacock-blue sateen, padded and quilted with pink sateen on the inside, and curtain to match, has an exceedingly pretty effect, and has been much admired: this by the way. Two balls of macramè cord will be required. Cut off into lengths of 10 ft. each. There will be few who are altogether unacquainted with macramè work, but for any who may not know how to set about it, I will do my best to initiate, and, with reference to the illustrations, I think any difficulty will soon disappear. Take the top cane and one of the 10 ft. cords; pass the ends under the cane inwards, draw over the top, and pass through the loop formed; under, over, through the loop again, as Fig. 5, A, and draw tight on to the cane. We have now two threads to work with. Place a second cord in the same manner, and draw close up to the first one. Leave a space ¾ in., and place two more cords, and so on all the way round. All the cords being placed in pairs at equal distances, a Solomon's knotted bar, of six double Solomon's knots, is to be made, four threads going to form one bar. I find the easiest way of working these knots throughout is to loop the two middle cords into a button-hole of the vest, and so leave both hands free to pass the outer cords from side to side. Fig. 5, B, shows a Solomon's knot before it is drawn tight. In Fig. 6 is shown a finished Solomon's knot and netting below second cane. Five minutes' practice will teach how this is done, whereas detailed directions would probably fail to make it any clearer. Having finished the round of Solomon's knotted bars, fasten on to the second cane by the macramè knot-stitch (Fig. 5, C). Remember, in doing this, that the first knot must always be drawn tight before the second is made, two knots with each cord forming one stitch. When the second cane is fixed, make two Solomon's knots beneath each of the above bars, and then proceed with the network. Fig. 6 will readily illustrate this. Take the two left cords of one knot and the two right cords of the next, and with them make two Solomon's knots, but drawing the first loosely in each instance; four fresh cords are taken each time. Work round and round in this manner until the depth of netting reaches 9 in. or 10 in.; then four or five more rows, gradually narrowing, by drawing the first knot higher up in each round. Fasten the cords on to the bottom cane in the same way as the one above—*i.e.*, with macramè knot-stitch. Cut all the cords to one uniform length of 5 in. or 6 in.; tie each pair together, forming half the number of loops. Now, from a piece of light strong wood ¼ in. thick, cut three bars 12 in. by ¾ in., and two bars 2 ft. 5 in. by ¾ in. Groove the ends for the cane to fit into, and fix as shown in Fig. 7, by lacing a length of cord through the loops previously formed, from side to side and from end to end, and draw up as tight as possible before fastening off. A

piece of stout ticking must be fastened underneath, and two eyelets to receive the hooks at ends of stop-strap.

Our part of the work towards supplying a swing-bassinette for baby is now completed. What remains to be done—draping, etc.—will be more deftly and nattily done by the willing hands of those whose pleasure it is to make babyhood a comfortable and happy time.

## CONSTRUCTIVE STRENGTH IN METAL WORK.

BY J. WHITFIELD HARLAND.

OBTAINING STRENGTH FROM PUTTING SEPARATE PIECES OF METAL TOGETHER TO FORM FRAMING—INVISIBLE FORCES IN ACTIVITY—ATTRIBUTES OF FORCES—VELOCITY—WEIGHT—TO DESCRIBE A PARALLELOGRAM OF TWO FORCES AND TO FIND THE DIAGONAL OR MEAN—THE IMAGINATIVE FACULTY—LIGHTNING CONDUCTOR—LATTICE GIRDER—ARCHED LATTICE GIRDER OF NEW CONSTRUCTION—BARS DECREASING IN STRENGTH PROPORTIONATELY TO LENGTH—IDEAL ARCH—CONDUCTORS—STRUTS—SECONDARY FRAMING—BOLTING THROUGH OUTER AND MIDDLE WEB-PLATES.

I HAVE endeavoured in two former papers to indicate the main points in achieving strength of construction in metal, and have spoken of the different strains and opposing forces, showing how their directions might be so deviated as to clash and expend themselves in neutralising one another, instead of acting in concert to destroy the construction itself. Fanciful, perhaps, I may have been in seeking to impress an image on the minds of WORK readers of the action of unseen forces in active operation, but this conception, if fanciful, is, in the main, absolutely true, and serves the purpose of stimulating the reasoning powers in the effort to foresee the results of the various expedients one must employ to overcome, by stratagem, as it were, the material obstacles that opposing Nature throws up against man. It is in this connection that I must emphasise the well-known principle of the diagonal of the forces, which we reduce to paper by making two lines square with one another, or at such an angle as represents the direction of each force, of such proportion to one another as shall express the value and activity of any two forces acting at the same time and in different directions. In arriving at this proportion it is evident there must be a unit of comparison, there must be a common denominator. One cannot compare chalk and cheese. All forces have two attributes: (1) velocity or speed, *i.e.*, feet travelled per second, and this involves what we term momentum (which is, after all, a mean between *inertia* and *propulsion*); and (2) weight. Hence, given the speed a certain weight travels per second in one direction, and given also the speed the ascertained weight travels per second in some other direction, and supposing the direction of each to be also ascertained and expressed accurately on paper by two lines drawn indefinitely long, one is now able to decide, by comparison, by simply multiplying the weight by the velocity in each case, to establish a unit of comparison between any two forces; the product of the one multiplication giving the one length of line, the same process giving accurately the length of the other. We have now only to complete the parallelogram by dropping perpendiculars, and draw a diagonal, which *must* be the mean of the two forces. To ascertain still further the complication of more forces than two, we can simplify the operation by the same process of elimination, obtaining the diagonal of any two, and then using the diagonals so obtained as data, and finding their joint diagonal, or mean co-efficient, which is the same thing.

It goes without saying that construction involves thought. As the Scripture saith, "Who by taking thought can add one cubit to his stature?" He cannot; but he has had the power conferred upon him—if he will study the all-wise laws which God has given for the government of the universe, not merely of what we call the earth, but, so far as we can see in our finite sphere of knowledge, of millions of other worlds visible only by our permitted knowledge of science—of manipulating such all-wise laws by his intelligence, and making them subservient to the good ends he has in view. Man cannot create, but he can construct; and whilst he may be defined by Carlyle as a "tool-using" animal, and by Sir H. Lyon-Playfair (in his opening speech at the late WORK Exhibition) as a "fire-using animal," and with all due deference to these high authorities, I prefer to define him as the *only imaginative animal* extant, and it is only by the exercise of this imaginative power that man has ever elevated himself and his kind. Therefore, it is by cultivation of the imaginative faculty alone that mankind can be educated to higher things; for neglected imagination, untrained, or badly trained, leads to the worst crimes; whilst on the other hand, the more thoroughly it is developed, the more it is brought under the control of reason and mathematics, and thus is compelled to act in strict obedience to the will and the conscience. The higher this high faculty becomes the more it will benefit mankind. All invention, all progress, all design—in short, all the influence that man can exercise over others for good or evil—depends wholly and solely upon the way his imagination has been trained. The genius of Shakespeare depended on this faculty; the whole system of jurisprudence, law tempered by equity, depends on the power of imagination, the power of putting one's self in the position of someone else; the power of knowing beforehand what is almost certain to occur in certain circumstances (and the worst of it is, that not in one single isolated case does our national system of education provide one lesson for the culture of imaginative faculties) is the function of imagination.

This digression is in defence of my mode of impressing on the minds of WORK readers the absolute necessity of forming an ideal in the mind of the hidden action of hidden forces which, to use a cant phrase, is "so much more easily imagined than described." Even such every-day phrases as "Fancy that, now!" "What do *you* think?" etc., show there is truth in this contention, for there must be a germ of it in the mind to cause such phrases to obtain currency.

Therefore, good WORK readers, please imagine that in the body of the metal in which you wish to work there are forces fighting against one another, or fighting against you, and that you must find out how to convert their efforts to nullify yours by taking advantage of the known conditions of their weight and their velocity and their natural direction, by pitting the one against the other, so that they may waste their initiative in overcoming, for you, other inimical forces without destroying the strength of your constructive scheme or plan.

To make this clearer still: you know, either by your own or by others' experience, that the electric fluid always seeks the shortest way to its opposite pole. In putting up a lightning conductor you provide the shortest cut to the earth, and thus render its passage harmless. In this case you simply have to contend with one force at one time. If you had two forces to contend with at the same time, the diagonal of the two forces, or three forces or more, ascertained as above indicated, would give you the direction in which the accumulative forces would elect to move; and if you provided in your scheme of construction a piece of metal lying longitudinally in that direction, as a path or channel wherein they might be jointly and severally conducted away, you deprive them of all power to injure your construction, just as the lightning conductor provides for a safe conveyance of the fluid to its other pole, instead of letting it run riot in its course to the destruction and ruin of your building which you thus protect. I say a piece of metal lying longitudinally advisedly, because, partly on account of the compressive resistance being greater than the cohesive resistance, and partly on account of the lengthway of metal being of greater dimension than any other, and therefore stronger, it is better fitted to form a way or channel between two points, without being itself injured, just as a road or street, having no obstructions and being hedged in, forms the best possible channel of progression.

The logical outcome of this theory is what is termed the lattice girder (see Fig. 1), in which what would, in a solid girder, be the two flanges, are two separate members connected together, not by a solid web as in the case cited, but by bars of metal which are riveted together and to the webs of the upper and lower members. Now to construct such a lattice girder properly, the bars which take the place of the solid web should possess the same resistance to strains of all sorts as the web would. If these bars were to be placed perpendicularly there would result an accumulation of force liable to displace them from the perpendicular, and the points of junction with the upper or lower webs would become so many fulcrums of leverage which the varied forces would immediately utilise. But, by ranging the bars in the line of the diagonal of the forces, they would be subject to no preponderance of any one force, and could carry off without effort or injury the whole of the combined forces longitudinally, conducting them to a safe outlet where they would become spent and harmless. Thus constructed, the framing constituting the girder can be made very much stronger than if it were made of the solid plate even of the same thickness as the bars, and this is not only a saving of material, but of a vast amount of weight to be carried, extra, which would increase instead of diminishing the strains of all kinds that would attack it.

I have, hitherto, spoken only of bars in the direction of the diagonal of the forces, viz.: *c*, *c*, *c*, *c*, *d*, *d*, *d*, *d*, in Fig. 1, but these are only the principal supports and the conductors of the forces, and would be incapable of resisting the remainder of the forces, as they could not, from their being at an angle to both top and bottom flanges, keep these two members invariably at one distance apart. We must, therefore, provide cross-braces, fixed to the centre of each diagonal bar or conductor, and to the webs also at each extremity of the bars (see *d*, *d*, *d*, *d*, Fig. 1), which braces or struts would prevent either end of the conductor from

moving on a pivot at its junction with the girders, and thus maintain the rigidity of the framing. In Fig. 1 it will be seen that the diagonal of the forces is shown to vary the further it gets from the centre of the girder it is part of. I ought to say that in the diagram it is only guessed at, the actual diagonal of the forces governing it not having been actually arrived at, as we do not presuppose any given data. It will also be seen that the conductors, as I prefer to call them, and the struts, are *slighter* in the centre than at the ends, *i.e.*, that as they become necessarily longer they require to be of proportionately greater breadth. Logically, this is correct construction, as the weight at the breaking point is reduced, while it increases the nearer it gets to the supports at each end. It will also be noted that the diagonal struts, *a*, *e*, *a*, *e*, *a*, *e*, are not only much lighter than the conductors, but are also proportionately heavier, as they require to be longer, which they become the further away they are from the centre. In short, every construction in the form of a bridge (which may be defined as construction supported at the ends only) depends for strength on its being capable of converting downward thrusts into compressive strains. This is done, as in every arch, by making the length of it greater than a straight line, which, so long as the piers or supports do not give way, can never, by any weight, be compressed or crushed till it only measures the length of a straight line from pier to pier. If the material of which an arch be constructed be such that downward pressure of any weight placed thereon, converted, at a loss of force, as it must be into a compressive strain acting outwardly from the centre, or keystone, in the direction of the piers, is capable of compressing it sufficiently to reduce its normal length to that of the distance between the piers, down it comes. The ideal arch, however, is one where each half or side is entirely self-supporting, irrespective of the other half, like two cantilevers independent of one another, each carrying away to the pier supporting it, and through it thence to the ground, the whole of the inimical forces. The nearer this ideal is approached the stronger the bridge, be it arch or girder, will become, because at the centre, which would be its natural breaking point, there is no strain whatever, and its stability would not be impaired even if it were broken.

In Fig. 1 I give what I consider to be the strongest means of strutting a lattice girder. Here the lower girder is flanged of an L section at bottom, and both conductors and struts are riveted to the opposite sides of the web; the web is double, with a centre web-plate. The top web is flanged at the top, and to this the conductors and struts are riveted—again leaving the flange intact. Instead of the conductors being solid, they consist of two separate pieces, riveted one on the outside of each of the webs, and the strut passes between the two. Instead of straight bars of sufficient strength for the conductors and struts, lighter ones may be used if they are dished under the steam-hammer to the section shown in Fig. 6, except where they require riveting. This would give sufficient strength to allow of them being thinner, not narrower. I am inclined to think that the struts should all be radial to the centre of the circle of which the arch is an arc, as shown, whilst the conductors form diagonals corresponding to the diagonals of the ascertained forces—and thus, denoting the distances apart of the struts, would connect the top of one strut with the foot of the next but one, and so on, always, however, maintaining the true proportion of breadth to length in both. In roofs, all ties and braces should, if possible, be bolted or riveted to the flanges, and not to the web; and in bridges, the flooring, which acts as both bracing and tie in one, should consist of buckled or dished plates bolted or riveted to the top flange of the upper member, not to the web already pierced to the full extent for the bolts and rivets of the framing.

In addition, is the latticing of struts and conductors, which I have shown shaded in the drawing (Fig. 1), so as to more clearly distinguish them from what may be called the secondary construction, which latter consists of the diagonal framing of the pieces *a*, *e*, *a*, *e*, *a*. *e*, which are riveted at top and bottom to the middle web-plates, *m*, *m* (see Figs. 2, 3, and 4), and to both conductors and struts where they cross them. But as, if these diagonals were made straight, being fixed at each extremity to the middle web-plate, they could not touch the outer framing on each side of them, consisting of struts and conductors riveted to the angle-iron portion of the top and bottom girders (the one straight, and the other, the lower member, arched), they must be cranked, so as to meet the outer or primary framing at the various points of intersection.

This construction has a two-fold purpose: it strengthens the whole fabric longitudinally, giving greater rigidity; whilst it also braces the two outer framings firmly to each other and to the middle web-plate, thus strengthening the fabric transversely. In order to connect the left and right angle iron webs with the inner or middle web-plate, these should be bolted right through between the ends of the struts and conductors, washers of the proper thickness being used in the interstices between them, as shown in Fig. 1. The end of the girder next to the abutment of the pier should be of the section shown in Fig. 4, and should not only be rivcted strongly to both top and bottom webs, but should carry also the end of the conductor, *c'*, the strut, *d'*, and the diagonal, *a'*, where they finish and die into it. The lower portion of it should be forged, as shown, to form a shoe at a radial angle to rest upon the springer of the

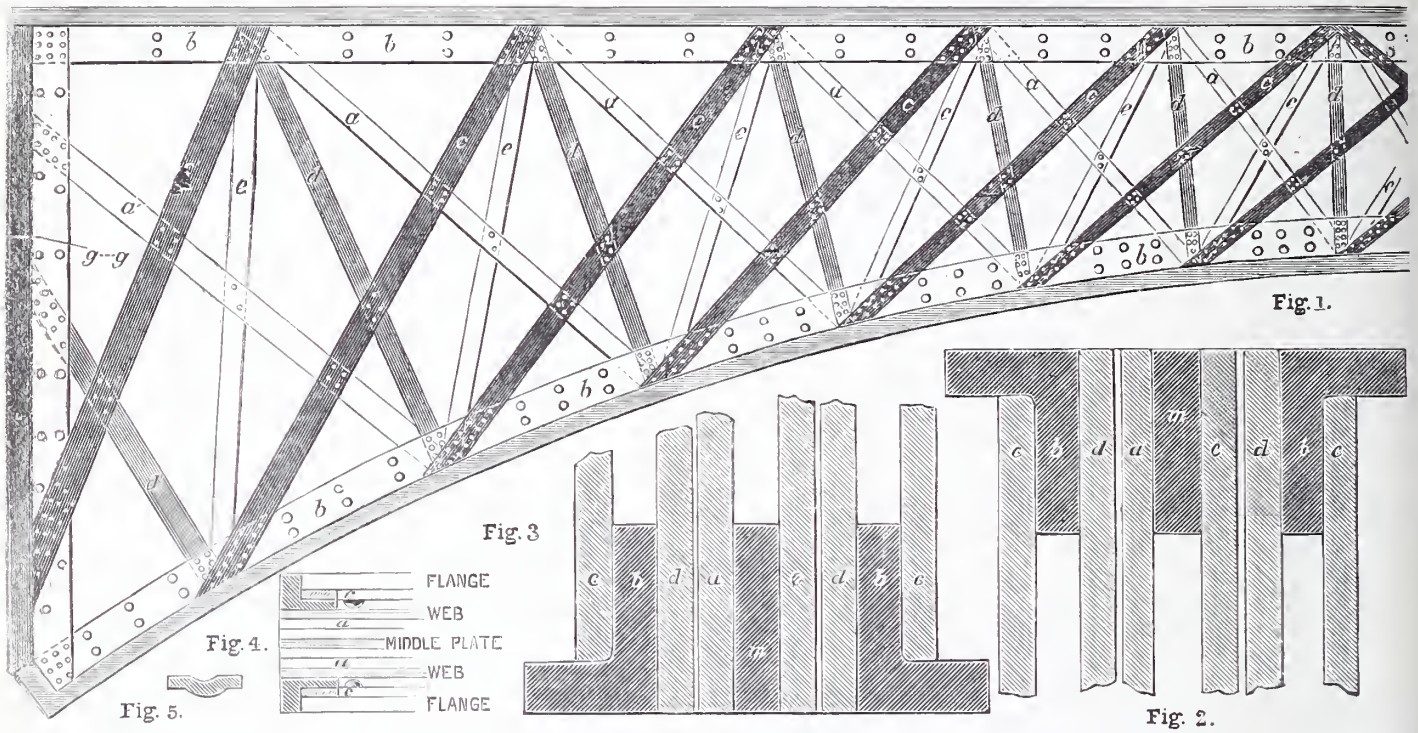

Fig. 1.—Half Elevation of Lattice Arch Girder—*a'*, *a*, *a*, *a*, and *e*, *e*, *e*, *e*, Secondary Diagonal Framing; *b*, *b*, *b*, *b*, etc., Web-Plates; *c'*, *c*, *c*, *e*, Conductors of Strains; *d'*, *d*, *d*, *d*, Radial Struts. Fig. 2.—Enlarged Section of Webs with Angle Flanges and Middle Web-Plate (*m*) of Upper Member. Fig. 3.—Ditto, Lower Member. Fig. 4.—Section at *g g*, Fig. 1. Fig. 5.—Section of Conductor or Strut, dished.

abutment pier. It should be mentioned that the whole construction should be of wrought iron, as cast webs would be too much weakened by bolting or riveting the struts, etc., to them, to stand any strain. Figs. 2, 3, and 4 are three times the size of Fig. 1, but none of them are drawn to scale, as none of the strengths have been calculated, and I do not presuppose any data. They are merely diagrams showing the general principle of construction only as applied to an arch girder.

## SOME ELEMENTS OF PATTERN-MAKING.

BY FRIDAY.

I SUPPOSE many a reader of WORK has had, or at some time or other will require, the iron-founder's aid in the execution of his work, the use of cast iron being so general that it is used in some shape or form in almost every craft represented in this paper.

But an iron casting cannot be obtained without its corresponding pattern is first prepared, and the intention of this paper is to put novices, either amateur or professional, on to the right track in the matter of pattern-making.

The average run of patterns sent to the foundries by amateur and professional workmen, other than those actually engaged in some branch or other of foundry practice, are constructed without any regard to the use for which they are intended. They are neat and well finished in many cases, but, from ignorance of a few elementary rules in pattern-making, are often quite useless as patterns, and have to be cut and altered by the founder before they can be used at all.

The first thing necessary to understand is the process known as "moulding."

Briefly, this is the art of producing, in suitable sand and under proper conditions, an impression of the required casting, which can best be obtained by ramming up in the sand a pattern or model of the article required.

Now, a moment's consideration will convince the would-be pattern-maker that this model must be withdrawn from the sand before the mould can receive the molten metal, and, therefore, the necessity of so making the pattern that it leaves the mould without disturbing the sand about it.

It is the non-appreciation and consequent non-application of this essentially fundamental knowledge that produces so many indifferent patterns from the hands of the amateur pattern-maker.

There will be cases in which a fuller knowledge of the art of moulding is required in order to construct a required pattern, but our paper is too limited in its scope to deal with such cases, our object being an explanation of the principles used in the simplest types, and leaving the reader to apply them to other and further examples.

It is obviously impossible to consider more than a few simple examples in this paper, though we fully expect to please but one in a hundred by our selections; and if this is so, we hope the ninety-nine will do no more than exercise their national privilege and grumble, as is the bounden duty of every aggrieved Englishman. The first thing necessary to pattern-making—given the tools and material, and, by the way, a pair of callipers are almost indispensable in this craft, and should be added to the ordinary joiner's kit if possible—the first thing to remember is that a pattern requires to be tapered, to allow for draft. To illustrate this, I append in Fig. 1 a sketch of a common pillow block, showing the taper on a rather exaggerated scale.

It will be obvious that such a model used upside down in the sand, as it would be, would very readily "draw" or leave the mould.

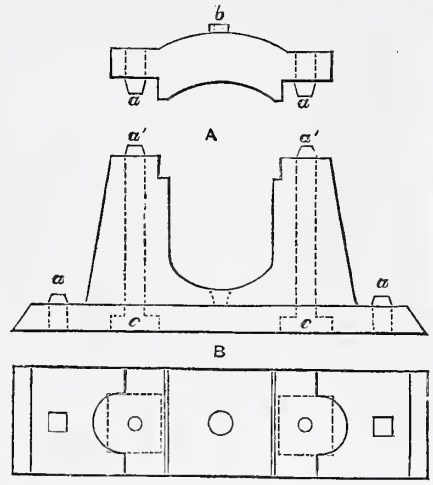

Fig. 1.—Pattern of Pillow Block and Cap, showing Taper in Elevation (A) and Plan (B)—*a*, *a'*, Prints for Cores; *b*, Oil Cup and Hole; *c*, Core Holes for Bolt Heads.

The same diagram illustrates another point—viz., the use of prints in pattern-making. These prints (*a*, $a^1$) are little pieces of wood, the size and shape of any hole that may be required in the casting: in this case for the necessary bolt-holes. It will be easily seen that a long taper core of green sand through $a^1$ would not withstand the metal when it is poured in the mould, but by use of a print an impression of the required hole is made in the mould, and a hard dried core may be stood in such a print hole, which will be strong enough to resist the inrush of metal.

It is not usually necessary to make the prints very prominent—just sufficient to supply a firm seat for the core. In our present example in Fig. 2, which is from a pattern for a 2 in. block, $\frac{5}{8}$ in. is the size, and even less would answer. The actual taper in the same model is $\frac{1}{16}$ in. all over: just enough to render moulding easy, without spoiling the shape of the block

Another simple example will illustrate two other elementary principles. The sketch illustrates a double-flanged cylinder. Here the hole is required right through; hence the prints are tacked on each end, thus providing a double support for the core, such a

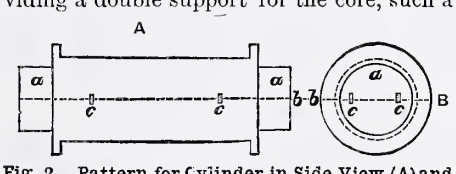

Fig. 2.—Pattern for Cylinder in Side View (A) and End View (B)—*a*, Prints of Cores; *b*, Line showing Cut through Centre; *c*, Pins for dowelling same.

casting being made on its side, as shown. Should the hole be required but partly through, one print will do, but it may be necessary to lengthen that one very considerably, unless there be no objection to the use of a chaplet at the inner end of the core. In either case it will be simply necessary to state the required depth to the moulder. Patterns of this type are much more convenient in use if they are cut in halves through the dotted line, and then dowelled together. They then part when the moulding box is uncovered, half remaining in the upper part and half in the lower part, thereby rendering their removal from the sand more ready and simple.

In the construction of patterns, glue suggests itself as a convenient article to use; but may I make one other addition to a well-known book of manners and morals, and remark that as far as possible in pattern-making, "Don't!"

Glue so frequently gives out when the damp sand comes into contact with it, and a pattern which possibly has taken hours to prepare often comes to pieces almost the first time of using, so that so far as possible the use of joiners' brads, or, better still, fine wood screws, is recommended as more likely to ensure the longevity in use of a pattern.

When, however, glue is necessary, it is well to use the very best; use it thin, and use it fresh. A little quick-drying linseed oil, well stirred in while the flue is quite hot, enhances its resistance to moisture; but even then a coat or two of a good oil paint is necessary to protect the joint from the moisture arising from the sand.

A word about core-boxes. Most founders have core-boxes, both square and round, varying from $\frac{3}{8}$ in. upwards, and the judicious use of the rasp or file will produce almost any plain core; but when the hole required in the casting is irregular, or peculiar in shape or position, a proper core-box will be necessary. Reverting to the "plummer" block, the hole through $a^1$ is required to contain a square head-bolt, as shown by the dotted lines at *c*, and the core will therefore take that shape; and a core-box for the same may be made by cutting away in two pieces of wood one half of the bolt, and then dowelling them together, leaving the ends open, so that the core sand may be well rammed into the space, from which they are subsequently removed, dried, and otherwise finished. In making core-boxes, the taper required for draft is similar, but opposite to that referred to in pattern-making. In making up dowelled patterns or core-boxes, it is very necessary that the joints should fit quite accurately, or the casting will be more or less irregular in shape, and out of truth.

A very important point in pattern-making is the due allowance for shrinkage. Castings in iron vary in shrinkage, according to their mass; for metal 1 in. in thickness, allow $\frac{1}{16}$ in. to the foot in making the pattern, while thinner castings require more, and thicker a shade less allowance.

Brass shrinks rather more, and $\frac{1}{8}$ in. may be substituted for the $\frac{1}{16}$ in. afore-mentioned. For castings under one foot, shrinkage need scarcely be taken into consideration; the rapping of the pattern by the moulder usually suffices. This rapping, which is done to loosen the pattern before drawing, is usually done by boring a hole in the pattern, and inserting a spike in the same, and then rapping the spike on all sides with a hammer. This necessarily tries the strength of the pattern, and if many castings are required off one pattern, it is well to cut a small mortise when the rapping hole is wanted, and insert therein a small iron plate with a hole in it, thereby saving the wood from the actual contact with the spike.

In making patterns of articles which have to be worked up before use, it is well to allow sufficient metal for the process. A file or lathe will easily remove a superfluous $\frac{1}{16}$ in., but no mechanical method can

satisfactorily add the same if it be lacking at the first. The material most used and most readily worked in pattern-making is undoubtedly pine or deal, and on the whole it is the best for most purposes, though a mahogany pattern soon repays its extra cost when a large number of castings are required from one model. In selecting pine, pick out the best-seasoned, but not the very driest and hardest, as these conditions develop into cracks and warps when in actual use.

To finish and preserve your pattern, the readiest and simplest method is a coat of hard-drying paint, which should afterwards be well sand-papered, and finally brushed well with dry blacklead or chalk. This gives it a fine smooth face, and renders it easy of use, and at the same time preserves it from the damp and moisture of the moulding shop.

Another preservative is a shellac varnish, prepared by dissolving one and a half to two parts (by weight) of shellac in twenty parts of methylated spirits. This takes longer to prepare and requires more skill in applying; and, on the whole, the first method is more simple and convenient to the occasional pattern-maker.

I find that, spite my efforts to refrain from the use of foundry phrases and terms, I have been compelled to use several trade terms, and would explain now that green sand is the sand usually found on the shop floor, and forming in use the main part of the sand; while a chaplet or frame is a wrought-iron stud, used to keep a core in its place in the mould. For example, the core of a column is often supported by chaplets, and their ends may often be seen covered by a little button on the columns of public buildings. Ramming up, rapping, draft, and some other words are, I think, sufficiently explained by their context.

In conclusion, the approximate weight of a casting may be arrived at by allowing fourteen pounds of iron to one pound of deal pattern, or eight pounds to one if the pattern be mahogany. Zinc castings are about the same, while copper, brass, and gun-metal are from twenty to twenty-five per cent. heavier.

## A CHAT WITH A FRENCH POLISHER.

BY "AMATEUR WORKER."

PRELIMINARY—REMOVING POLISH FROM HANDS—WORKSHOP HABITS—NAPHTHA POLISH—MAKING POLISH — AMATEUR *v.* PROFESSIONAL POLISHING—STAINING.

LIKE many readers of WORK, my favourite hobby is working in wood, making odds and ends of furniture, and such like. Now, as an amateur, I like to finish my own work, and to do so of course I have to change myself from a cabinet-maker to a polisher when the proper time arrives—that is to say, I do the work of the latter instead of that of the former. As I am supposed to know a good deal about polishing, I am often appealed to by friends of kindred tastes to my own to help them out of their difficulties. Sometimes I am able to do so, sometimes not; for whatever I may or may not know about the work, I do not delude myself with the notion that I know *all* about it. There is always a little more to be learned, and when that has been done, still something further—a kind of "Will-o'-the-Wisp" chase, extending the field of operations, but not getting hold of finality in the particular line of work. I am, however, more fortunate than some, inasmuch as I have many acquaintances among professional workers, and when I am in a difficulty they are generally ready to help me out with it.

Well, to come to the point, I have an old friend, a beardless youth of fifty years of age, or thereabouts, who has been a French polisher all his life; though, strangely enough, even he does not profess to know *everything* in connection with his trade. He is, however, always willing to give any information he can, and is a reader of WORK.

Sitting together one night lately, and a copy of WORK lying near him, some remarks were made about it, to the effect that he saw Mr. Denning was writing on "Polishing," and that this seemed, to judge from the "Shop" columns, to be a subject in which many readers are interested. The conversation became general shop—I mean polishing shop—talk, though I am bound to say it was all one-sided, my friend W—— doing all the speaking, and I the listening. It was a regular lecture on polishing, considered generally, and I said to him after a bit—

"W——, why don't you put all this down on paper, and send it to the Editor of WORK?"

He replied, after a few thoughtful moments, which were apparently occupied solely in filling his pipe—

"Well, you see, there is nothing in what I am saying except what everyone knows, and Mr. Denning will, no doubt, tell anything that is important before he has done."*

I could not agree with the first part of his remark, for there was a good deal in what he was saying which I am sure interested me, and would, no doubt, be equally interesting to others could they have heard him. As for the rest, possibly Mr. Denning may not think it worth while to touch on such general topics in his series of articles on Polishing; and, in any case, I do not think he will object to seeing these remarks regarding polishing viewed from a different side to his own. I am inclined to think he will be very glad to see them published. Finally, I suggested to W—— that if he would not write to WORK, I should. Agreed; and this is the result. I do not pretend to give the words, only the general tenour of what was said.

The opinions are those of an experienced polisher, who served his apprenticeship, worked as journeyman, and for many years has been foreman over a number of others. They are, therefore, worthy of attention; and the writer has the privilege of being the mouth-piece, or rather the pen-holder, which makes them public in WORK.

The observations are made in the first person, my friend W—— being the speaker, and my own remarks are left out, to be read between the lines, if necessary.

"I often wonder why amateurs bother so much about polishing, for it seems dirty work for a gentleman to take up; and though I like it very well as a trade, I don't care about it for amusement; but then, I suppose no one does look on his own business as being a pastime. It's his work, and by way of a change he takes to someone else's when he has done with it. My hobby is photography, and I daresay a photographer would think this anything but an amusement, so that, after all, there is not much wonder that amateurs, when they have made anything, like to finish their work. The dirt—or it's not that so much as hardened polish and other things on one's hands—can easily be washed off with a little (methylated) spirit or soda and water. No, I don't mean spirits and soda-water internally. Yes, it's a fact that some men will drink even methylated spirit if they can't get anything else, though it is horrible stuff: nothing better than poison. They will even suck it out of the spirit-rubber if they get the chance. It is best not to have too much of it about. There is no risk of youngsters learning bad drinking habits from the polish or spirit used; though, of course, if they are in a shop with dissipated men they may get spoiled, but that would be the same in any business. The fumes from the spirit are not strong enough to hurt anyone.

"It was different with naphtha when it was used instead of spirit, for the vapour affects the eyes. Naphtha, anyway, is nasty stuff. It smells horribly, and is not so safe as spirit. Why, in a full, close shop at the end of day one could see the vapour flashing as it came in contact with a light. I should never use naphtha when I could get spirit. I prefer to make my own polish, and, whatever the books may say, there is nothing better than shellac and spirit. Some of the bought polishes are very good, but I like to make my own, for then I know exactly what it is. That is the principal reason why good polishers prefer their own preparations, even if they use something besides shellac and spirit. Opinions differ, and men have their fads in polishing as well as in anything else. Then there is a good deal in a man being accustomed to his materials. I think the chief reason why polishes often contain something besides shellac is on account of price. Take resin, now; it seems to give a better substance and body to the polish, but it is cheap. Polish with much of it in will not stand well, and something is put in to make it more durable and work better. I have never been in a polish manufactory, and do not know what manufacturers use, so I don't want to run them down; but I don't see how a lot of the low-priced polish can be sold, unless it is adulterated. It really does not much matter what kind of polish amateurs use; for, of course, they can't get as good a finish, even with the best, as a regular polisher, though they often seem to think they ought to, and wonder why they can't. They blame the materials, and perhaps something may not be just what it should be, but the chief reason is want of practice. How can an amateur or beginner reasonably expect right off to do what a polisher has to learn during a long apprenticeship, with those over him to show him how to do anything? It is unreasonable for anyone to think that he can know all about polishing at once. Even if he is told, and may have all the ways and methods clearly explained to him, he still wants practice. Even among polishers there are plenty 'not worth their salt' when they have to do anything but plain straightforward work, such as staining, matching-up, and the like. Anyone can do staining—after a fashion—but to do it thoroughly a man must have used his eyes and his brains. He must have studied the different kinds of timber, with their varieties of marking, not only in colour but in configuration. He must enter into the spirit of the different features, so that he can convey the impression of the wood he intends to represent. There is nothing

* I have in my hands papers from Mr. Denning on "Spiriting-off," "Glazing," and "Dry Shining," in connection with French Polishing, and these will appear in due course.

mechanical about this kind of work; simply copying will not do, though for purposes of study useful knowledge is gained by doing so. A man may know all about staining so far as the most useful colours and the preparation of the stains, but may signally fail in using them properly. Anyone can wash them on, and so darken the wood to the same extent all over; but then, if an imitation of a darker wood, except as regards colour, is wanted, this is not sufficient. The characteristic markings are absent, and it is certainly better to let them be so than to perpetrate the hideous libels on the real material which are so often seen. Then, again, even in colour there are minute differences which can be got only by adapting the stain at the time, modifying one with a little of another, and so on. All stains must be used with discretion, and one cannot tell another how to apply them with equal success always, even on the same kind of wood, for in any, great variety will be found. To take one, now very fashionable—viz., mahogany. It varies in texture and colouring very considerably; and supposing we want to stain it a 'Chippendale' colour, even after the exact darkness of this is known or specified, to get several pieces equally matched, the stain must be strengthened or reduced at the discretion of the polisher. How is it possible to explain to anyone else exactly what will suit all the pieces, even in one piece of furniture? It cannot be done. Just the same might be said of oak, or almost of any wood.

"Then amateurs make a lot of fuss about having different fillers and different little preparations for varieties of woods. Of course, each polisher has his favourites, but then he could manage very well with any of those generally used; and it is almost nonsense for a beginner to think that he could have managed better if he had used something else to fill or polish with. It is only a man who has been constantly at the work who can appreciate the differences between one material and another for the same purpose. So you see, after all it is principally experience that the amateur or beginner lacks when he cannot do polishing properly."

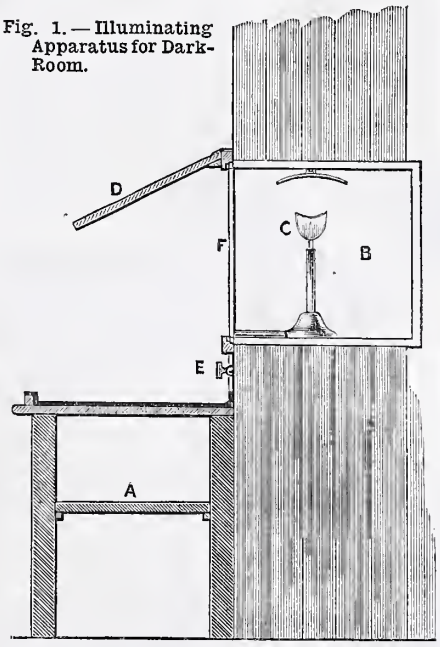
## LIGHT FOR THE PHOTOGRAPHIC DARK-ROOM.

BY WALTER E. WOODBURY.

PRELIMINARY CONSIDERATIONS—UNHEALTHY AND INJURIOUS DARK-ROOMS—REQUIREMENTS OF A PERFECT LIGHT—A SIMPLE ILLUMINATING APPARATUS—NO LIGHT ABSOLUTELY NON-ACTINIC.

BY far too little attention is paid by photographers, either amateur or professional, to the subject of dark-room illumination. Perhaps to the amateur, who practises the art but little, making a photograph but now and then, the subject is one of little interest, as any lamp will do, provided it be perfectly non-actinic, and give sufficient illumination for his purpose. But there are many, however, who remain for considerable lengths of time shut up in a room lighted only with a ruby or yellow light. In this case, two important conditions must be studied if the health of the worker is to be considered. First, with regard to proper ventilation; and, second, the injurious effect of the light upon the eyes. It cannot be disputed that remaining in a dark-room, usually of very confined limits, for any length of time with a light burning, and no proper ventilation to carry away the noxious gases formed, can but be extremely detrimental to the health. Again, too few have any idea of the injurious effect constantly looking at a red or ruby light has upon the eyes, producing eventually a form of congestion. Taking these two points into consideration, I have devised a form of dark-room lamp that should, I think, meet with all requirements. These may be briefly stated to be: first, a light that will not produce fog on a sensitive plate on reasonable exposure; second, that shall throw a sufficient quantity of light to work by upon the dish containing the negative where the light is required, and that shall be shaded from the eyes of the worker;

Fig. 1.—Illuminating Apparatus for Dark-Room.



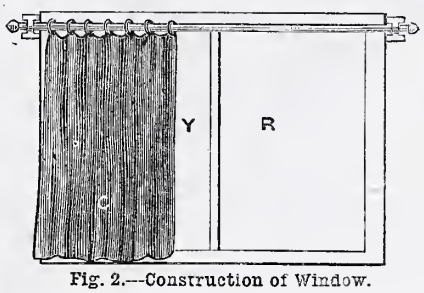


Fig. 2.—Construction of Window.

third, that shall be outside the dark-room, yet capable of being controlled from a convenient part inside; and, fourth, that shall give intensities of illumination varying at will with the necessary requirements.

In Fig. 1 I have endeavoured to give a sketch of an illuminating apparatus that fairly well meets all these requirements. A is a bench with a leaden sink top; B is a box or chamber fitted outside the dark-room, preferably with a special outlet for the vitiated air; C is a gas flame, the size of which can be controlled from the outside by means of the tap E. The light passes through the coloured media at F, and is reflected on to the working table by means of the reflector D, which has also the effect of shading the light from the eyes. Fig. 2 will serve to show the construction of the window through which the light passes. Two pieces of glass are required, one a canary-yellow colour, and the other of a ruby-red. In front is arranged a curtain of black material. With this arrangement, it will not be difficult to see how the strength of the light can be altered at the will of the operator by shifting the position of the opaque curtain. For developing very sensitive plates, the curtain is drawn completely over the yellow glass and half way over the red. For working bromide paper, or with the material of low sensitiveness, the yellow glass will be found suitable. This can also be used for examining the plate during the progress of development.

It should always be remembered that there is no medium which is absolutely non-actinic. The deepest ruby light will fog a plate if it only be allowed sufficient time for action.

Therefore every care should always be taken that it is not exposed to the light more than is absolutely necessary. A cover should always be placed over the dish when it is not required to examine the plate. Another advantage gained with this light is that at any time, if desired, the whole room may be illuminated for convenience in finding articles placed about. For extra convenience in this, the reflector D should be hinged so that it can be lifted out of the way. This is also necessary when examining the progress of the negative.

The window should also be removable, for exposing bromide paper and lantern and transparency plates.

The construction of the whole apparatus is not very difficult or costly; and I claim that those who work for great lengths of time in the dark-room will find it invaluable.

## BOOT AND SHOE REPAIRING.

BY WILLIAM GREENFIELD.

INVISIBLE PATCHES ON UPPERS—HOW TO BLINDSTAB—THE FINDING OF THE HOLE INSIDE.

THE neatest of patches is what is called an "Invisible Patch." It is stuck on with a solution of gutta-percha. Its solvent has a very unpleasant smell, but as it evaporates very quickly, it is not smelt much by the one using it; but if used in a room with the door shut, it will soon be smelt by whoever opens the door. To do this part of the business, an outhouse is best, or any way, when no one is near.

This solution can be bought at 2d. per bottle, and when not in use it must be kept well corked. Worman's has a scent mixed with it, so it does not smell quite so bad; but I prefer Sand's, not for smell, but for quality.

I will now show how to fit the new patch on the old leather. First, it is of all importance to have a last, boot-stretcher, tree, or something in the boot, that the part you are going to operate on may be quite solid.

But before going further, it will be best to state that during these articles I have, and shall have, often cause to refer to what in the trade is called "skiving." It is a thing that is so essential; therefore, I here advise all who do not know how to do it well, to try their hand at it as much as possible upon any old odd piece of upper leather, with a sharp knife, on a piece of smooth marble or board. Skiving means: to give a tapered edge to the leather, on one side or the other, and skiving is the principal thing in this sort of patch, for it is fitting it to a nicety that makes the patch invisible.

The safest way to get the piece the right size is to cut a piece of paper out, about

¼ in. larger all round than what is really necessary to cover the worn or cracked parts, or than what you would in the ordinary way. This is to admit of the skiving. Then, seeing that this is of good shape, cut the new piece of leather to it. This should also be as described in the last article, "Calf for calf, kid for kid," etc. After the piece has been cut out a nice oval or curved shape (Figs. 1 and 2), proceed to skive the edge. Skive all round, if oval; and round the top only, if curved (Fig. 2). It should be skived from the letters A A A to the edge, B B B, and at this part it should be positively skived to nothing.

The difference between preparing these patches and one to be closed in is that the new piece is fitted first, and after the old leather fitted to it, and that the old piece of leather is not taken away, as for closing in.

It will only be necessary to explain how to put on the oval piece in this instance, for in all other shapes the rule is the same, excepting where the pieces have to be sewn down to the sole; and instructions for this were also given in the preceding article. Now, when the piece is skived, lay it on the worn part of the boot, overlapping the worn part equally all round, as A A (Fig. 3), which is a section of the patch. Now chalk the edge all round, and on the old leather as well, as shown at B, and draw a line right across, as at C C, that you may get the piece back into its proper position.

Then skive the old leather, at D D, just enough to receive the patch, starting at the edge of the chalk mark, and skive towards the centre, all round, being careful to get it regular.

Then nicely rough both the new and old leather with a file, piece of coarse sandpaper, or scrape with a buff-knife. Now lightly brush out all the dust of leather, and apply the solution with the finger; shake the bottle and give one thin coat, both to the patch and old leather; let them dry, and then give another coat, but only thin; let this dry. It should dry white, and if it does not do so, it will need a little more solution. Care should be taken to see that the edge of the patch has taken the solution properly, and that the old leather has it only on the rough part.

It may be considered that it would be best to solution a patch like Fig. 1 all over, but it is not so, as it would make it very stiff, and it would not yield in wear, but only perhaps wrinkle and soon work off. The whole of the solutioned part having dried white, warm both before a very slow fire, and when the whole of the white has changed its colour to a brown, stick the piece on the boot, just as you first fitted it; press it on tight, and, with an iron only just warm, iron on a little soft heelball all over; let it get quite cold, then gently rub off the heelball, smooth with a cloth, and polish with blacking, and it is finished.

Our next system of repairing the tops is "Blindstabbing," so called from having to find the hole inside a boot, where it is impossible to see. Blindstabbing is one of the most important things to learn regarding the repairing of the tops, inasmuch as all repairing to the tops can be done by this means in one form or the other—as patches, rips, toe-caps, new springs, etc., etc.

One thing it is very handy for indeed, and that is when a vamp has (which is very often the case) a small crack in it. You can darn this up in two different ways. First, with using two ends, and setting a zigzag stitch from one side to the other, as at A (Fig. 4); or by setting the stitches with one end only, as at B. This is by far the neatest way of

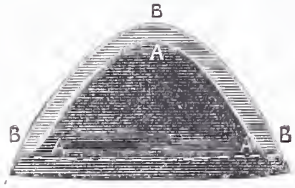

Fig. 2.

Fig. 1.

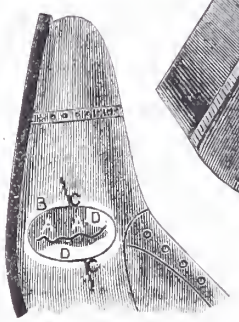

Fig. 3.

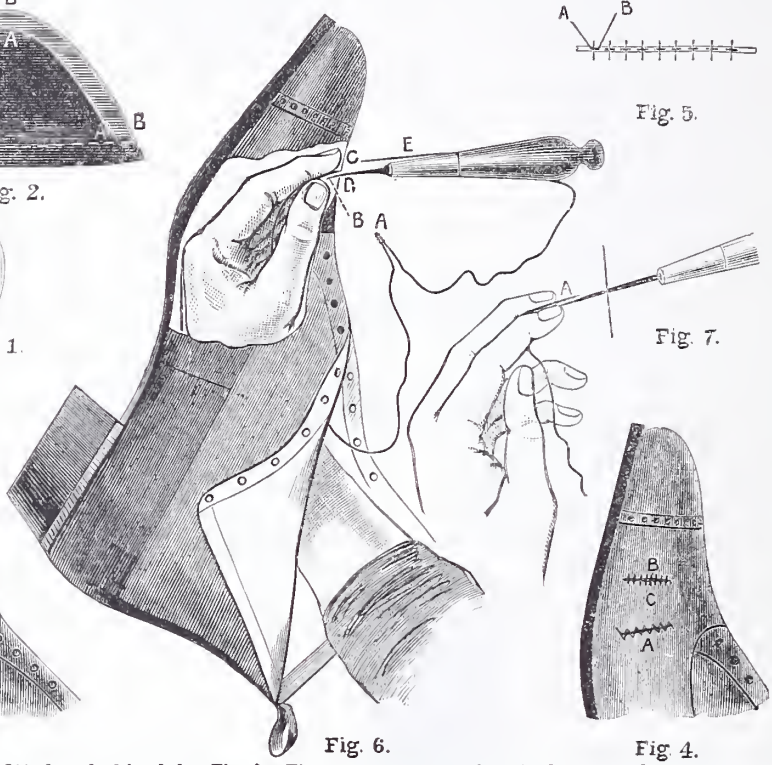

Fig. 6.

Fig. 5.

Fig. 7.

Fig. 4.

**Fig. 1.—Patch fitted and skived for Fig. 3. Fig. 2.—Patch that has to be sewn down to Sole. Fig. 3.—Portion of Boot showing how to fit Old Leather to receive Solution. Fig. 4.—Showing how to mend Crack by Zigzag Stitch and Cross-Stitch. Fig. 5.—Full-size Sketch of Cross-Stitch. Fig. 6.—Boot with Hand inside, showing how to find Hole by using Awl as Leader. Fig. 7.—Another Method for Out-of-the-Way places, and for those whose hands are large and not lissom.**

Fig. 6, it will be seen, is to illustrate the way to do blindstabbing. The left hand must be put inside the boot, with one of the bristles between the thumb and finger, with the point of the bristle about level with the tip of the finger. The stab-awl, which is an awl with a thin, straight blade, is held in the right hand, and at the same time holding the other bristle. It is well to first put the two bristles together, and halve the thread; give it a twist, as at A, so that both ends may be the same length in working.

The awl is then put through about halfway, and its exact position felt with the finger of the left hand, and then lay the bristle parallel with it, as at B; place the finger against the lining of the leather at C to steady the hand; draw out the awl within about a quarter of an inch, pushing up the bristle with it, and letting the bristle lie on the flat side of the awl; and keep moving the awl up and down (not in and out), and the bristle with it, until the point of the bristle finds its way into the hole with the point of the awl. It is quite easy to keep putting the awl up and down if the first finger of the right hand is kept on the leather at C. When you find the bristle in the hole at D, pull the bristle and end through with the right hand; hold it in the hand with the awl, as E; put the left hand in the boot again with the other bristle; make a second hole, and repeat, as shown above, till the bristle is in, and then put the right one through. Take the right one (E) in the left hand, and the left one pull out with the right; pull them both out together the whole length of the thread, pulling somewhat sharply; then give a second pull, just to tighten the stitch. The first stitch is set, and this is continued as far as necessary, putting from twelve to eighteen stitches to the inch.

The position of the boot, as shown in Fig. 6, will give the student the knowledge of how it should be held upon the knees; but while drawing out the thread, it will have to be held fast between the legs, with the toe against the right knee and the heel against the left thigh, and this according to where the repair is being made.

It may be noticed here that all methods of doing anything has been, and will be, explained for a sitting posture, unless specially notified at the time.

When it is wanted to sew up towards the toe, or anywhere out of the way of the position of the hand in Fig. 6, there is another means of doing so. This is by holding the bristle between the first two fingers, as Fig. 7. The bristle is put on the cushion of the second finger, and held there with the nail of the first, as shown at A.

To blindstab like this is more difficult to the two, but, like anything else where an advantage is to be gained, it needs more care and attention to make it so.

In either case it is well to put a piece of leather under the crack. It will want skiving at the edge—in fact, Fig. 1 would do very nicely. It is very easy to get under if it is rolled up and passed through the crack, then levelling by putting an awl through and unrolling it, and then seeing that it is exactly under the crack.

In darning it, set each stitch from B to C (Fig. 4), but taking hold of no more on either side than you can possibly help; and when this is done the whole length of the crack, start stitching backward, setting the stitches from A to B (Fig. 5), which is a full-size sketch of the crack and stitches. This second stitching is to draw down the first row, and make them look small. A fine end or piece of twist should be used, and when it is lightly hammered down, and a piece of soft heelball rubbed in, it can scarcely be seen.

learn, but, it being so very useful afterwards, it well pays for the extra trouble.

Boys can soon learn to blindstab, as their hands are small; and it is a thing that will always be of use to them, and a good first step to industry as a pastime.

## SMOKY CHIMNEYS AND HOW TO CURE THEM.

BY "EXCELSIOR."

WHERE THE FAULT LIES—USUAL MODE OF SETTING RANGE—COURSE TO BE ADOPTED—PROPER FORMATION OF FLUE—REGISTER GRATE—USUAL AND PROPER MODE OF SETTING AND FORMING FLUES—REDUCTION OF CHIMNEY FLUES AT TOP—INSUFFICIENT SUPPLY OF AIR TO GRATE.

Most people, in trying to cure a smoky fireplace, look for the fault at the wrong end of the chimney—viz., at the top.

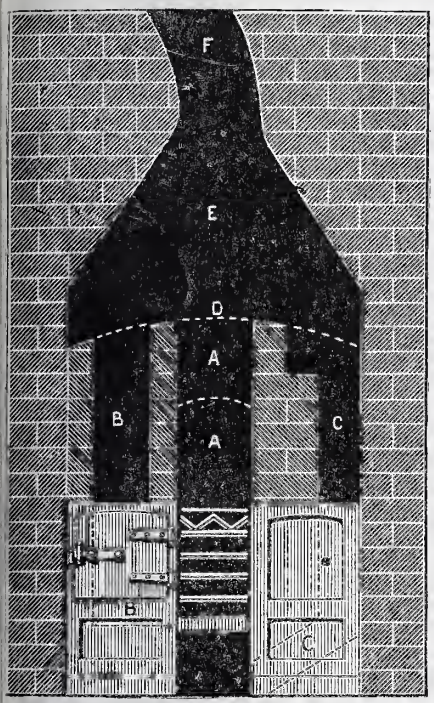

Fig. 1.—Usual but Improper Method of setting Oven Grate or Range. In this Fig. and Fig. 2 the Iron Back and Chimney-Breast are removed to show Construction of Flues. A A, Main Flue from Fire; B B, Flue under and behind Oven; C C, Dust Flue; D, Level of Top of Grate Back; E, Drum or Open Space into which Flues discharge; F, Chimney reduced to proper size.

I venture to assert that, in nine cases out ten, the fault is at the bottom, and rests with the setting of the grate, and I will show that this can be cured by the outlay of a very few shillings.

When building the house, the workman makes the opening to receive the grate the full width, height, and depth of the grate intended to be used; he then gradually tapers off the opening inside till he reduces it to the size of flue required, which is generally about 14 in. by 9 in., which size is reached about 3 ft. above the top of opening left for grate, as shown at E in Fig. 1.

Now for the setting, or fixing, of the grate. We will take, first, the oven grate or range—whichever is intended to be used. This is set up in the opening, and the flue, A, from fire in the centre, and also flues B and C from oven and boiler, are carried up separate to about 6 in. above the top of the

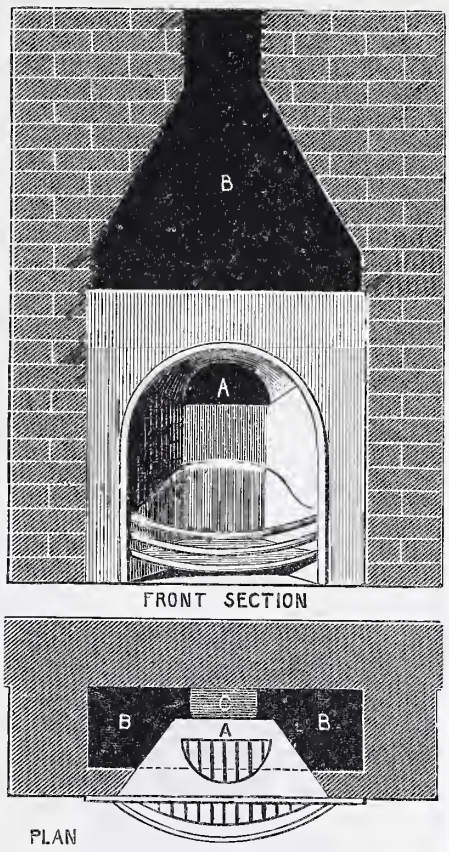

Fig. 3.—Usual Way of setting Register Grate; Chimney-Breast removed—A, Lid of Grate; B, Drum or Open Space round Grate; C, Bricks as Back of Grate.

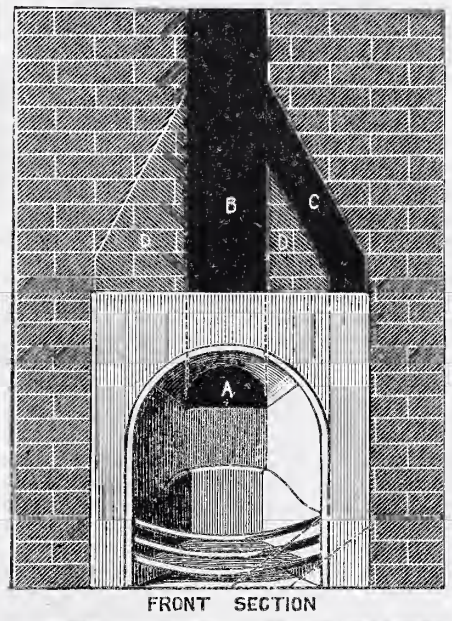

Fig. 4.—Proper Mode of setting Register Grate; Chimney-Breast removed—A, Lid of Grate; B, Flue from Grate; C, Dust Flue; D D, Proposed Brickwork forming Flues.

grate or range, where they all discharge into the gathering, or taper opening, E, between the top of the grate and the flue proper.

Here lies the fault. Here is a large open space or drum, in which the smoke, so to speak, wanders aimlessly about, interfered with by currents of air, instead of making its way at once up the flue and away, at the same time losing much of its heat, thus making it still more difficult for it to ascend quickly. As will be at once seen, this can be easily cured by getting rid of this open space.

To do this, get a bricklayer to start the centre flue from the grate at the same size,

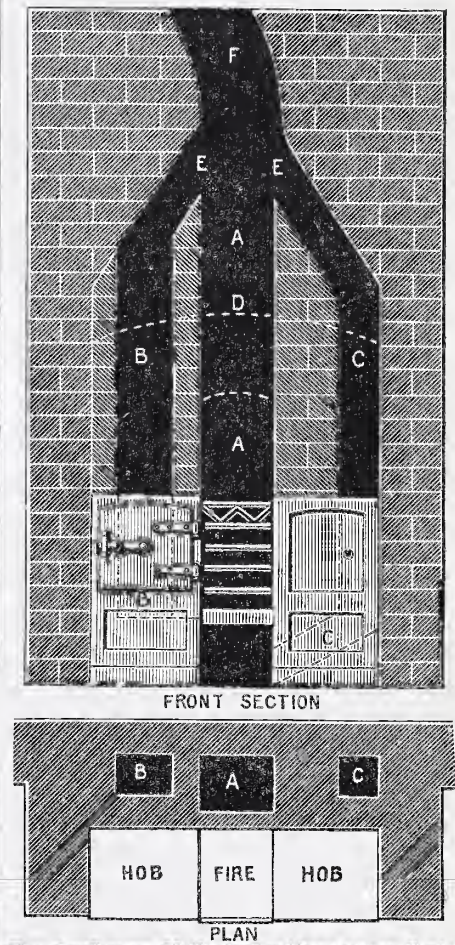

Fig. 2.—Proper Method of setting Oven Grate or Range, shown in Front Section and Plan; Iron Back and Chimney-Breast removed—A A, Main Flue from Fire; B B, Flue under and behind Oven; C C, Dust Flue; D, Level of Top of Grate Back; E E, Diagonal Openings of Side Flue into Main Flue; F, Chimney reduced to proper size.

or, preferably, a little less in size than the flue above, and carry this up until it joins the flue above, at the same time carrying up and bringing nearer, in the same manner, the side flues from ovens, etc., until they join the centre flue through an opening in each side, as shown in Fig. 2.

Carry these side flues up as high as possible before joining the main flue, as this will give a better draught to them. Another advantage of this is that the openings into the centre flue being vertical, falling soot cannot get down them, blocking them at inaccessible places. The truth of this will be seen by looking at E E, in Fig. 2.

Now with respect to that abomination called a register grate, generally used in the

sitting-rooms or parlours of middle-class and the better class of workmen's houses.

These, being constructed so as to be complete in themselves, are oftentimes worse fixed than oven grates, which must of necessity have some brickwork. I have been called to some scores of register grates, to find them just placed in the opening below the chimney, with, perhaps, three bricks behind them to support fire-brick back as shown at C in Fig. 3, and all the remaining space, B B, round and above them being left open.

What else can we expect from a grate set like this but smoke and annoyance?

To cure this, have the whole space at back and sides filled up solid with brickwork, as shown at D D, Fig. 4, of course forming the flue, C, from dust-hole on one side, and then start the smoke-flue, B, at once off top of grate (leaving just room for the lid, A, to lift up), and carry it up to where the chimney is reduced to its proper size, as described before, bringing the dust-flue, C, into it at one side, and having the mouth of it vertical, as in the oven grate or range.

Another advantage of having the grate made solid behind will be that a greater amount of heat will be radiated into the room, which before penetrated through the sides into the space at back, and was lost up the chimney.

Again, pay particular attention to the fact that the smallest place in a flue should be immediately over the grate, as the farther smoke travels the more heat it loses, and consequently the more room it requires in which to get away.

This brings us to the consideration of chimney-tops.

A few months ago my attention was called to a chimney on which pounds had been spent without any improvement. I had the flues carried up as directed, which made an improvement, but not a perfect cure.

I then examined the top, and found the flue—which was a 12 in. circular one up to that point—reduced to 7 in. by a chimney-pot. The removal of this completed the cure.

Yet another failing may be insufficient supply of air: this is readily supplied by piercing a few holes in the hearthstone, immediately in front of the grate, and connecting these with the outside of the building by means of pipes laid in the floor.

If these simple suggestions are carried out, they will cure the majority of smoking chimneys; if they do not, some special cause must be looked for—such as position, whether surrounded by high buildings in such a way that there are gusts of cold air beating down on top of chimneys. Such chimneys would require special treatment—only to be decided by a study of the special causes.

Should the subject be thought of sufficient general interest, I will at an early date give details for constructing a simple, cheap, and most effective grate, in place of the ordinary register.

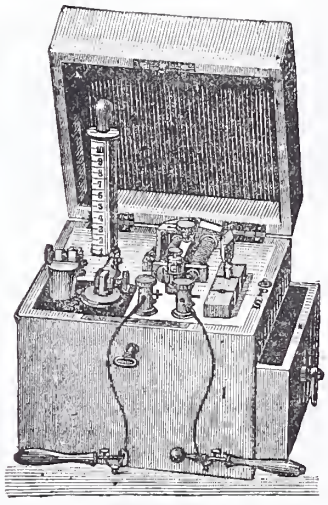
[As the cure of smoky chimneys, and the construction of grates on a simple and efficient plan, are subjects which are interesting to all householders, it is hoped that "Excelsior" will soon redeem the promise made in the last paragraph. The present time is an opportune one for the appearance of papers of this kind, for there is ample time to act upon the advice given and to get the work of reconstruction completed before the time for lighting up fires has come round again.—ED.]

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 43.—SCHALL'S ELECTRO-MEDICAL APPARATUS AND INSTRUMENTS.

I HAVE received from Mr. K. Schall, Medical Instrument Maker, 55, Wigmore Street, London, W., a copy of his new illustrated price list, and a specimen of the medical coils made by him. The neat little coil sent is known as Dr. Spamer's Induction Coil, and is enclosed in a polished mahogany box measuring five inches square. The box contains a small glass cell, fitted with zinc and carbon elements to form the bichromate battery for actuating the coil; a small vertical coil, with movable iron core to regulate the strength of the current, and a drawer containing conducting



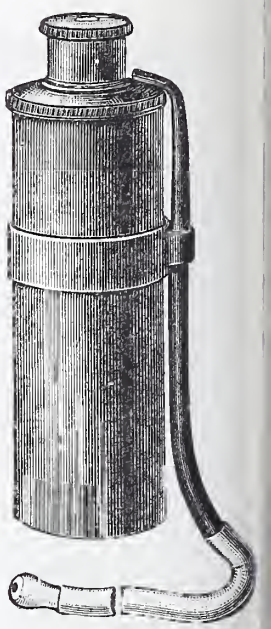
**Dr. Spamer's Induction Coil.**

cords, several rheophores, a pair of polished rheophore handles, and a set of spare zinc plates for the battery. This bijou electro-medical coil is well suited to the requirements of a county practitioner needing a portable means of applying a faradaic current to his patients, since the whole can be sent by parcel post for 9d. This will give some idea of its lightness. It is furnished with a separate quick-acting rheotome of the horizontal form, and very sensitive in action. The faradaic current from the secondary coil is, therefore, of a mild character, easily borne by a child of tender years when the coil is actuated by a current of 1½ volts, even when the core is fully in the coil. Every part of the apparatus shows good workmanship, and is well worth the two guineas charged for it. Mr. Schall has been engaged for several years as a maker of electro-medical apparatus to the London and provincial hospitals. He is now open to supply the medical profession generally with high-class apparatus at a reasonable price. Medical gentlemen interested in this subject should obtain his new illustrated price list of 128 pages, which contains some good information on galvanometers, electrical measurement, the care of galvanic batteries, and a list of books on electro-medical subjects, published in the English, French, and German languages.

### 44.—GLASS-TOPPED SPECIMEN BOXES.

The boxes known by this name have been very recently brought into the market, and will be found useful by a great variety of persons for a number of purposes, which space forbids me to attempt to enumerate at length. They were shown to me for the first time a few days since by Messrs. Moseley & Son, 323, High Holborn, London, W.C., who supply them in the four sizes in which they are made—namely, No. 1, at 2s. per dozen: No. 2, at 2s. 6d. per dozen; No. 3, 3s.; and No. 4, 4s.; all post free at the prices named. The diameter and depth outside measurement of the four sizes respectively are as follows: No. 1, 1½ in., ⅝ in.; No. 2, 1¾ in., ⅝ in.; No. 3, 2¼ in., ⅞ in.; No. 4, 2¾ in., 1 in. The boxes are neatly made, and present a pretty appearance, some being of a dark gold colour and others like frosted silver. The method followed in making them is ingenious. First of all, two pans are made of equal diameter, the upper one having the top edge neatly turned over to take the glass top, which is dropped in on it. A narrow ring of metal, resembling a flat indiarubber band, is then dropped in on the glass, and is held in place by points of metal driven in by pressure from without. A broad ring of bright tin is then put into the lower pan, and projects above it. The cover is then closed down over this ring on to the lower part, and the box is complete. The boxes are made on Jahncke's patent, and presumably come from Germany. Entomologists will find them useful, and so will all who need receptacles for small articles, such as screws, fittings for fretwork, etc.; for, as the contents of the box can be seen without removing the cover, much of the trouble will be saved which invariably ensues when such articles are stowed away in pill-boxes or match-boxes.

### 45.—JONES'S PATENT "MULTUM IN PARVO" SPIRIT LAMP AND BLOWPIPE.



**Jones's Patent "Multum in Parvo" Spirit Lamp and Blowpipe.**

The accompanying engraving shows very clearly the appearance and construction of this useful and appropriately named "Multum in Parvo" Spirit Lamp and Blowpipe, made on Jones's patent, and supplied, post free, by Messrs. Moseley & Son, 323, High Holborn, London, W.C., for 4s. The lamp itself, including the top, is 5 in. in height and 1½ in. in diameter. The cover of the top unscrews, and when put on is screwed down on a washer of yielding material, so as to prevent the escape of the spirit within. The blowpipe, as may be seen, is bent inwards towards the flame at the upper and smaller end, and outwards at the lower end, on which is fitted an indiarubber pipe about 15 in. long, with a bone mouthpiece. It will be found to be a most useful and handy article by gas-fitters, plumbers, etc., and all who are frequently obliged to make use of a blowpipe. The flexible indiarubber tube and mouthpiece with which it is fitted admit of its use in many places where it would be impossible, or, at all events, difficult, to work with an ordinary blowpipe applied to a flame from an ordinary lamp. It can also be used with advantage as a torch or light, when working in dark places, by unscrewing the loose top. The lamp is charged by filling the cylinder with lamp cotton or cotton waste, which must be saturated with methylated spirit for light work, or with benzoline for heavy work. The blowpipe is inserted in a brass band which can be moved up and down at pleasure. Thus the blowpipe can be adjusted at any height up to 2¾ in. above the top. THE EDITOR.

## SHOP:

A CORNER FOR THOSE WHO WANT TO TALK IT.

*** In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**House Gas.**—E. F. B. (*Liverpool*).—I am not aware that coal-gas has been liquefied. It consists of a mixture of gases, of which the chief are hydrogen, marsh-gas, olefiant-gas, and carbonic oxide, and each gas requires a different amount of pressure to liquefy it. Thus, whilst marsh-gas requires a pressure of 180 atmospheres at 7° centigrade, hydrogen requires 650 atmospheres at −140°C. (One atmosphere is 15 lbs. per square inch.) Very powerful machinery would be required for this, and these gases are only liquefied for chemical research. With regard to your other question, the following gases and vapours will not burn: nitrogen, carbonic acid gas, steam, and, in some senses of the word, chlorine.—F. B. C.

**Ornamental Bookcase.**—BOOKWORM.—Bookcases have had a fair share of the space of WORK. Through Vols. I. and II. you will notice by the indexes there are several, although whether any of them are ornamental it is for you to decide. There are also one or two in the few numbers already issued of Vol. III. Look diligently through "Shop."—J. S.

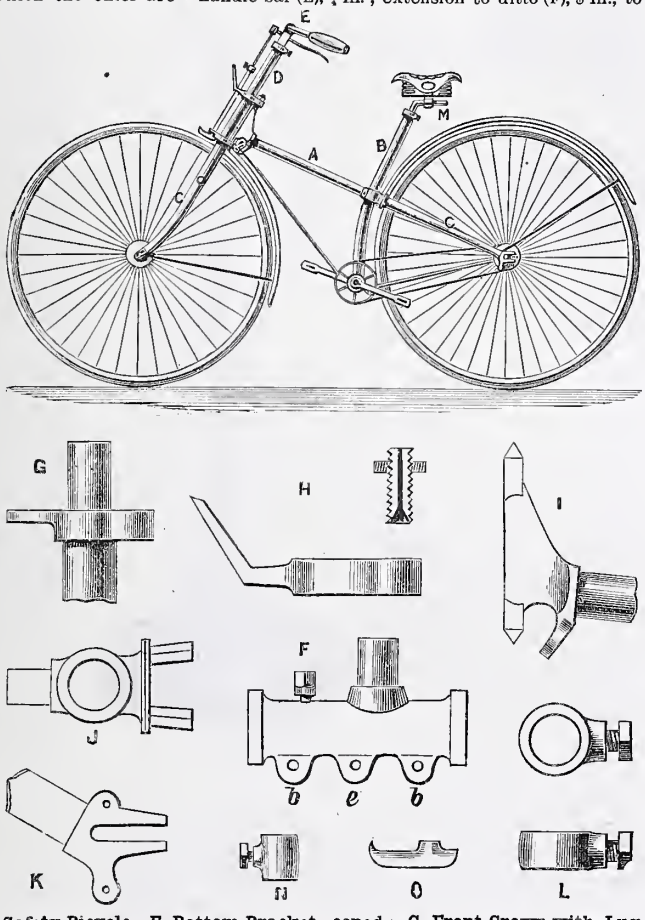
**Home-Made Printing Press.**—AMATEUR PRINTER.—To describe the construction of such a press for amateurs, with the necessary drawings, would take too much space for the columns of "Shop." Wait for a short article.—S. W.

**Gelatine Slab for Copying Writing.**—PATRON.—Gelatine, ½ lb.; glycerine, ½ lb.; a little French chalk or sulphate of baryta to give opacity, and sufficient water, form the composition used for this purpose in the Scriptograph.—S. W.

**Planing Wood.**—R. J. (*Monkland*).—You have in your letter indicated the great difficulty of manual work and the chief defect of printed teaching. I fear "Shop" is too crowded for a long lesson. As a daily teacher, I find that no progress can be made until the critical faculty is awakened. You evidently have that. Now, what is a flat surface? And how can we test a surface to ascertain if it is flat? A flat surface is one which is touched everywhere by a straight line applied to it; no matter in what direction the straight-edge is applied, it should touch the surface throughout—be in contact. I suppose you will try to make a straight-edge? You can have no better lesson. Do it in two ways. (1) Fix together two thin boards by means of three or four screws. Try to plane the edge of the board thus formed as straight as you can; take out the screws, and bring the planed edges into contact. See if they touch throughout; if not, replace screws and try again, noting what fault you discovered, and try to remove it. (2) Plane the edge of a board, and, using it as a ruler, draw a line; turn it over, and bring it up to the line. See if it agrees, knowing, as you do, that two straight lines cannot enclose a space. When you are successful in making a straight-edge, keep it for testing your work, but do not expect to obtain quite accurate work on wood which is thin enough to bend under the pressure of the plane. Thin boards need careful treatment and a flat bench. In the article on Piano Back Making there is embodied an excellent lesson on planing.—B. A. B.

**Indexes of WORK.**—A. F. L. (*Manchester*).—The numbers after each article refer to the *pages* of each volume. Quote the page and the volume to the publishers, Messrs. Cassell & Co., Limited, and you will be able to procure any number you require. Each number consists of 16 pages; therefore the process of division by 16 will give you the number containing any special article: thus, page 34 by 16 will make it clear to you that page 34 will be contained in the *third* number of any volume. But why not subscribe regularly for so small an outlay as one penny per week?

**Safety Bicycle Model.**—J. G. (*Aberdare*).—The parts to make the machine shown in the sketch can be had of Brown Brothers, 7, Great Eastern Street, or St. George's Cycle Company; or in Birmingham of W. A. Lloyd, Lionel Street. All the above will send their price list of materials. To make a cheap machine the bearings would have to be plain or coned, not ball. Cheap lap-welded tubes can be had, but I should recommend weldless steel. In the sketch the wheels are 30 in. by ¾ in., direct No. 10 spokes, forty in the back wheel and 36 in the front. Backbone (A), 14 in. by 1¼ in.; upright seat tube (B), 18 in. by 1¼ in.; two pairs brazed hollow forks (C, C); front steering-tube (D), 12 in. by 1¼ in.; handle-bar (E), ¾ in.; extension to ditto (F), 8 in., to fit inside steering-tube (D). The stampings are: Front crown piece (G); two lugs, with screw for fixing neck (H); neck (I), to be fitted into forward end of backbone (A); centre bracket (J), through which passes the upright seat-tube, and to which are fitted backbone and rear forks; two fork ends (K), one having extension for step; two lugs (L), one to fit on top of steering-post, other on top of seat-pillar; L pin (M), to fix saddle, should fit inside seat-pillar.



**Safety Bicycle—F, Bottom Bracket, coned; G, Front Crown with Lug in one; H, Upper Lug with Lamp Bracket; I, Neck; J, Centre Bracket; K, Fork Ends; L, Lugs for Top of Steering-Post and Seat-Tube; N, Brake-Rod Clutch; O, Brake Spoon.**

**Workman's Clock.**—T. A. (*Old Kent Road*).—Thanks for your ideas on the subject. If you will turn to page 699, No. 95, Vol. II., of WORK, you will find your idea fully described and illustrated. Workmen who may wish for a few ideas on electric time alarums to call them up in the mornings, will find them in plenty on pp. 157, 175, 226, 416, 582, 699, and 723, Vol. II., of WORK.—G. E. B.

**Incubators.**—SUNDERLAND.—Your query being somewhat of a business nature, if you will send me your address under cover of the Editor, I will write you privately.—LEGHORN.

**Framing Engravings.**—J. B. (*Manchester*).—There are many modes of framing good engravings (etchings, mezzotints, and line). I will describe two of the most artistic. (1) Suppose that what you describe as the tinted border (properly called the India paper) measures 17¼ in. by 12¼ in., you should procure a panelled strainer 23½ in. by 18¾ in. You will see that this allows a margin of 3 in. all round. You must then cut down your white outside paper to such a size as to leave two to three inches to overlap the strainer on all sides. Sponge the back of the print, paste (round edges, say, 3 in. only), and lay down on strainer. (2) Strain as above; then get an overlay Whatman mount, either white or French grey. Cut the opening with bevelled edge, to show the engraving itself only if it is without India paper border; if with, show the border, and allow 3 in. to 3½ in. margin of mount on all sides equal. You need not glue mount down, for in fitting up frame it will set all right.—F. B.

**Manganese for Leclanché Cells.**—R. L. (*Ruabon*).—The manganese used in charging the porous pot of a Leclanché battery is the common black ore of manganese, named in some districts "black wad." It has also the names pyrolusite, binoxide of manganese, and peroxide of manganese. It has a black colour, something like rock powder, and must be used in grains of this size, or about the size of peas, for the purpose of charging the cells. If this is the variety found in your locality, use it in charging the cells, but sift it free from dust before putting it in the cells.—G. E. B.

**Standard Ohm.**—J. N. (*York*).—The standard ohm recognised by the Board of Trade is a small instrument for measuring the resistance of electric currents. It consists of a length of German silver or of platinoid wire having a resistance nearly that of 6 ft. of No. 36 pure copper wire. This wire is made into a coil, mounted on a bobbin, and furnished with suitable terminals. I do not suppose you could make one yourself, as you have not the necessary appliance for ascertaining the exact resistance of the wire.—G. E. B.

**Medical Coil.**—G. T. (*Hollinwood*).—I think you have committed a serious error in undertaking to treat patients with doses of electric current from a medical coil before qualifying yourself in electro-therapeutics. I can easily gather this from the contents of your letter. You may be an expert in medical botany, but you know little or nothing about the use of electricity in the relief of pain and cure of disease. If you will take my advice, you will abandon the use of the medical coil until you have studied well how to use it by reading some good books on the subject. Get first "How to Use a Galvanic Battery in Medicine and Surgery," price 4s., published by Messrs. J. and A. Churchill, London. Then read "Electricity in Medicine and Surgery," price 8s. 6d., published by Messrs. Smith, Elder & Co. You will find other useful books in the lists of these publishers. When you have read the first two, you will not need ask anyone the questions put in your letter. Instructions on making medical coils are given in my last paper of the series on Induction Coils. Much harm may be done to your patients by wrongly applying to them the electric current from a medical coil.—G. E. B.

**Faulty Dynamo.**—C. T. B. (*Chapel-en-le-frith*).—I should have been glad had you made your letter long enough to include the sizes of wire used in winding your machine. The cause of failure to light a 5 c.-p. lamp with your machine is evidently due to want of current. This may be caused by an insufficient quantity of wire on the armature, or this driven too slowly. In either case the voltage of the armature current is not high enough to send sufficient current through the F.M. coils to magnetise their cores. You must therefore drive the armature faster. Very little current can be got out of a small machine when driven under 3,000 revolutions per minute. Have you tried shifting the brushes until the best working angle has been obtained? As you have the F.M. coils in shunt with the armature, you will gain nothing by placing a shunt in the main circuit.—G. E. B.

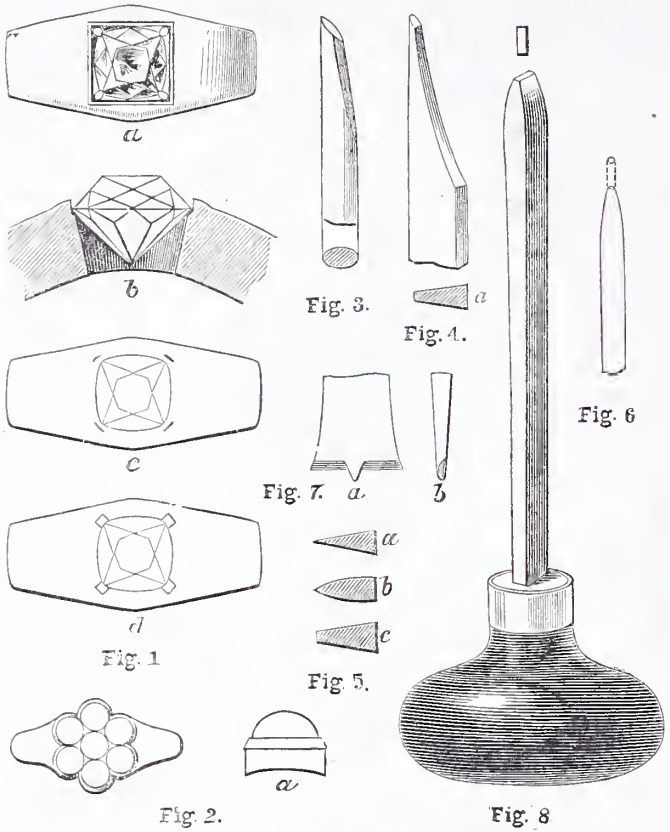
**Repairing Medical Battery.**—J. W. N. (*Gateshead*).—Scrub the zinc block clean, then put it in a saucer or shallow dish, and pour on it a mixture of one wine-glassful of sulphuric acid to four wine-glassfuls of water. Pour on the water first, then the acid, slowly and carefully. The mixture will get scalding hot. Next pour on the zinc about an ounce of quicksilver, and turn the zinc block about in the mixture until well coated with the quicksilver. When it has cooled a little, brush off all surplus quicksilver from the zinc, and put the mixture with the quicksilver not used away in a bottle for future use. This process is called "amalgamating the zinc." You will have to repeat it whenever the zinc gets black and dirty. Charge the cell with 3 oz. chromic acid and a wine-glassful and a half of sulphuric acid in one pint of water. The chromic acid can be obtained by post at a cheap rate from Mr. S. R. Bottone, Wallington, Surrey.—G. E. B.

**Boot Tools.**—A SNOB.—The best shop for kit tools is C. F. Jupp, 78, Wardour Street, Oxford Street, London, W. He will send you anything you need, and I know his kit cutter is one of the best, and each piece is ready for use. His seat wheels are 5s. each, fore-part irons 1s. 3d., double irons 1s. 6d. Should you require further prices, send for list. See WORK, No. 87, Vol. II., page 568. I answered question to M. M., the last of which explains how to cut a fore-part iron. If you do not think you could re-cut the tools you have, it will show some of the essential points to be noticed in buying new.—W. G.

**Making Hinges.**—BUTT.—The substitution of one material for another in manufacture is not the subject matter of a patent. An inventor may

prepare and lodge some papers, and receive a certificate from the Patent Office that he has done so, but this is *not* protecting an invention. An inventor who has no means to pay for having his work done in a proper manner by a duly qualified person must be content to find out by his own exertions whether his invention is new, or what part of it has been forestalled; and then comes the proper preparation of the documents, so that they shall properly explain, define, and cover his rights. This, it is needless to say, cannot be done by one inventor in ten thousand. It seems to us that the section would have to be cut into the lengths required, and then drilled, which, with proper apparatus, there should be no difficulty in doing. We are not quite sure that we have not seen something of the kind proposed before, but cannot speak decidedly off-hand. The only course open to BUTT is to get someone to take an interest or share in his invention and provide the means, so as to be able to have a property created in it. The mere fact of a patent being granted in response to an application no more makes it a property, or proves it to be such, than does an idea of a railway to the moon show how it is to be done, or prove that it can be. If BUTT will refer to No. 41, Vol. I., of WORK, page 694, he will there find some information respecting patents of which he, inventors, and the public have little or any knowledge, but which is of the first importance to all persons desirous of creating a property in inventions.—C. E.

**Diamond and Pearl Setting.**—H. C. (*Norwich*).—This answer will be kept to the particular kinds of setting for which details are asked; but as any attempt at describing the art of setting will probably fail without actual demonstration, I trust that H. C. will write again if he finds some particular point overlooked or not described sufficiently. There are no details of preparation of the work asked for, except on one point, and that is: "Are rings, etc., coloured and scratch-brushed before setting?" No absolute rule can be given for this, but it is well, when we can, to leave the scratch-brushing of all work until the very last, because the surface of coloured gold is so delicate that ever so little rubbing deteriorates it. As these processes can neither be done with stones set with either painted or foiled backs, it follows that the article must therefore be coloured and scratch-brushed before setting; hence we have to do the best we can to protect it with goldbeater's skin. With such stones as pearls, turquoise, corals, etc., no harm should come to them when being scratch-brushed after being set, neither will it harm any stone set with an open back; but do not on any account risk getting water under such things as rose-diamonds by leaving scratch-brushing until the last with them. In short, just think of the particular conditions of each job, and act accordingly. A word as to holding the work during the process of setting. I strongly advise putting all work on a cement-stick, or shellac-stick if the latter be preferred. (Jewellers' cement can be bought at about 6d. per lb. from most tool and material shops.) By this means the article can be held firmly, and does not get out of shape, as many things do when held between clamps, rings particularly. If the work is wrapped round in goldbeater's skin, it must be dried before being put in the warmed cement-stick. It saves trouble if care is taken to keep the cement out of the holes, hall-marks, carvings, etc. This is, of course, done by the "goldbeater" when used, but by paper or whiting in other cases. Another tip to prevent the cement sticking to the work is to pass the very thinnest film of oil over it. This is what would be done with most bright polished work. Now to try and write down all the important steps taken to set (1) a diamond in a ring square-set; (2) a pearl cluster with bright bevelled edges—*i.e.*, glass setting; (3) a pearl cluster with cut down grain setting. No. 1. Fig. 1, *a*, *Square-set Diamond Ring.*—To open the ring for the stone, first drill a hole right through, and let it be a little smaller than the stone. Then open the hole: I mean that the top edge of hole is to be made exactly the size of stone, then file out the hole quite clear to the back, and polish it. See that the ring is polished now before the stone is set, which is the next step. Fig. 3 shows the way a buhl-sticker should be ground and sharpened for use in opening holes or for "letting in" stones. This tool is made to cut round the hole and partly downwards, thus clearing out the hole at the same time that it opens it to the stone. Letting the stone in means that the girdle of the stone is to be made to rest on a bearing, which is to be cut at such a depth that the edge or girdle of the stone is just below the top edge of the gold. This condition depends on the preceding one, for if a stone be correctly "opened to," then merely cutting the gold out below the edge will bring everything right—that is, if the correct depth be obtained. Fig. 1, *b*, indicates this condition in an enlarged section. The next thing to do is to hold the stone in the ring. This will be done by the aid of a medium-sized round scorper ground like Fig. 4. This tool is forced in the gold at four places as marked (Fig. 1, *c*), and the portion of gold between the notch thus made and the stone is pushed forward towards the stone until each piece in turn is over the stone. These pieces, which are rudimentary grains, have to act as points or claws to hold the stone in. That being so, a suitable distance must be chosen for the first hollow that is made by the round scorper, and must, of course, be well within the square we intend to make. Next to "clear away the sides of the grain," a knife-tool (Fig. 5, but sharpened like Fig. 4) is used to make the side cuts, which will leave the work like Fig. 1, *d*. If the grains be not sufficiently over the stone, they can now be pushed up by applying pressure at their bases. The stone now is practically "set," as far as safety is concerned. All that remains is to finish the work, by using the knife-tool to make the grain to the desired size, and then to cut the square with a bright spit-sticker (Fig. 5 *b*), finally finishing it all with a grain tool. The ways to brighten or "gloss" a scorper are many. The one given here is an easy one. It is by making a buff of a piece of very finest emery-cloth glued to a piece of wood, on which the surface that is to be brightened is rubbed until quite smooth, and then the same surface should be rubbed on what is known as a piece of "black-stone." This is to be obtained at tool warehouses as a rule, but failing that, a smooth piece of lump emery, followed by a leather buff charged with putty-powder or rouge, will give a fairly good bright surface. As to the grain tool, it must be of suitable size, of course, and can be made out of a piece of steel rod, like Fig. 6, the end of which does not come to a point, but has a very smooth, rather shallow hollow in it. On the true shape and the surface of this tool the finish of the grain will depend. A most necessary tool for keeping grain tools in order is a fion. This is but a row of different sizes of hard, bright, round steel points, which act as burnishers to the cup-like, or, rather, saucer-like hollow of the grain tool. No. 2. *Glass Setting a Pearl Cluster.*—Fig. 2 is intended to represent a pearl cluster, the gold setting of which is finished in the form of a bright bevel. It is done as follows: The pearls are let in with the utmost care as far as fitting is concerned; and if the mount in which they are to be set be a deep one, then a buhl-sticker can be used as before; but as a rule, pearls and such-like stones are set in a plate of about $\frac{1}{32}$ in. in thickness, so in its place a round scorper is used, ground and sharpened diagonally. This can be used to open the hole from the commencement, but it is better to make a few "pearl" drills, with points the shape of Fig. 7, which, as you see, is not so likely to go through a thin plate as a spear-drill would be; and, besides, it clears the hole out, and if made the exact size, will not only open the work, but almost let the pearls in, if they are quite round in shape. Before fixing the pearls, it is well to put a layer of very fine plaster of Paris all over the bottom of the hole, not to stick the pearls in with, but to give a level surface to rest the pearls on, and to keep dirt away from the backs. To fasten these, a tool shaped like Fig. 8, and made of soft steel roughened on its face by filing, is used. With this "pushing tool" the gold is forced up to and over the edge of the stone. When the gold is close up, then a flat scorper (Fig. 5, *c*) is used to cut a bevel all round it, as shown in Fig. 2, *a*. This bevel is to be bright cut, and to brighten the scorper, the same process is gone through as was done with the bright spit-sticker in the previous job. This setting, from its very simplicity, is a very difficult job, and will take much practice before the settings are properly finished. No. 3. *Setting a similar Cluster with a Cut down Grain Setting.*—The stones are to be "let in" and the gold pushed over, as in the preceding case. Then proceed to mark the places with ink where the grains are to come, and cut away some of the gold in between the grains. Then push up the gold once more, and be sure that all round the stone the gold is quite close. All that remains is to trim the grains into shape, and cut down the parts between them with a similar bright scorper to that used in the second job, finishing off by nicely grain-tooling the tops of grains. The shape and proportion of grains are shown in some of the illustrations on "Ear-Rings," which were printed in preceding numbers of WORK. All the tools here drawn are given merely as types, not especially for the particular size required, although they are sketched from tools actually in use. The art of setting is one that almost teaches itself, as far as its principles are concerned, but practice and experience are the chief factors of one of the sections of jewellery manufacturing in which good wages are still earned by competent men. And I may say, in conclusion, that, like poets, good setters are born, not made.—H. S. G.



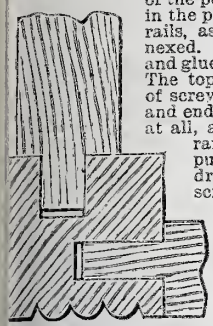
**Diamond- and Pearl-Setting Tools. Fig. 1, *a*.—Drawing of Square-Set Diamond Ring, enlarged. Fig. 1, *b*.—Showing relative Positions of Stone and Top Edge of Ring. Fig. 8.—Full-size Sketch of Pushing Tool; this also shows a good length for all the other Scorpers, of which points or sections only are given.**

**Wood Photography.**—J. M. (*Kilmarnock*).—The tools you require may be obtained at Buck's, in Tottenham Court Road, London, or Moseley's, in New Oxford Street, W.C. Photographing in wood may be done in several manners. The chief condition to be borne in mind in adopting any process is that it shall be as much *on the wood* as possible. A thick film of any kind is a fatal objection, as it chips off in cutting. The best plan is a transfer in greasy ink from a collotype cliché. Another plan is to put a thin even coating of salted gelatine mixed with zinc white, sensitised by brushing a strong solution of nitrate of silver on the dried gelatine surface: dry, and print under an ordinary negative to the proper depth, and fix with hyposulphite of soda: wash and dry. This is a process very frequently adopted. Certain precautions must be taken to prevent the wood warping. All the parts of the block not to be printed on should have a coat of some waterproof varnish. In washing, only the printed surface should be moistened with water, the block being held in the hand, and the water applied with a soft brush. This carefulness to avoid excess of moisture applies both to salting and sensitising, strong solutions of each kind being used. Salting solution is made of bromide of ammonium, 20 grains; gelatine, 5 grains; water, 1 oz.; oxide of zinc, 1 drachm. The silver solution is nitrate of silver, 90 grains; distilled water, 1 oz.; citric acid, 5 grains. Fixing solution: hyposulphite of soda, 1 oz.; water, 4 oz. The block must be allowed to dry spontaneously by standing it on its edge in a current of dry air. Artificial heat, such as holding it to the fire, will cause it to warp, and be useless for printing. This process is easily worked, and very good results may be obtained with ordinary care.—D.

**Cameras.**—CAMERA.—Some time may elapse before such a paper as you ask for on camera construction can be presented, so much having already appeared in the body of WORK and in "Shop" upon the subject. If, in the meanwhile,

ou want a thoroughly good camera, you cannot do etter than write to George Hare, 26, Calthorpe treet, London, W.C., who does excellent work.

**A Small Sideboard.**—NEMO.—The gable rails re 1⅛ in. thick, and are set back ⅜ in. from the face of the posts. The mortises are cut in the posts for the front and end rails, as shown in the sketch annexed. These are fitted closely, and glued fast to keep them firm. The top is secured by a number of screws, all from the front, back and end rails—none from the posts at all, as you seem to think. The rails are pocket-holed for this purpose, as shown in the drawing. Perhaps two screws in each end rail and four in front and back rails will be as many as anyone need wish for, and will be quite ample for the purpose. Oak is certainly the better wood for such a job as this is, as

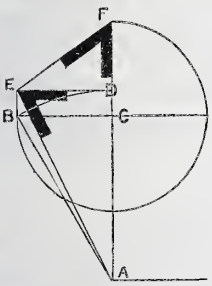


Sideboard Mortises.

ar as appearanee goes; but mahogany decidedly easier to work, as it is less ritty. Good Spanish mahogany is the est to use, though of course it is the earest. I am sorry I cannot recommend ny of the firms you speak of, as perонally I know none of them. You can-ot go far wrong, however, in dealing vith any respectable merchant; and if ou care to do so, you can see and get rices of wood from several before purhasing.—N. M.

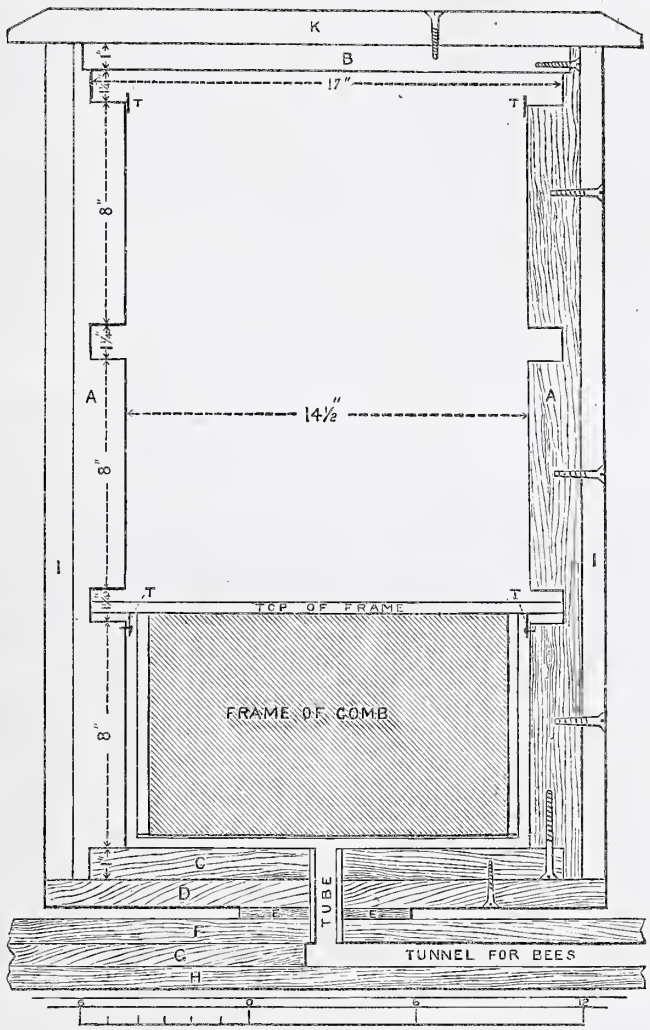
**Stains.**—J. M. (*Fulham*).—I know of o book devoted entirely to stains for vood. Most works on French polishing isually devote a few pages to the subect. Perhaps Mr. Denning may do so n the series of articles on French polishng appearing in the present volume of VORK. To give full particulars of *how* nd from *what* stains are made to imiate the various woods and self-colours -such as black, blue, green, etc.—would ake up more room in "Shop" than I hink the Editor can spare at present. f, bowever, you will write us again, tating any particular stain or colour ou may require, we shall be happy to ssist you.—LIFEBOAT.

**Bevels for Dovetailing.**—SIDEOARD.—Set out angle of sides on a rawing-board. We will call the angle ection angle, said section being at right ngles to base, B C on diaram. Square p from A. utting top line t C, with A as entre and A B s radius, describe are, cutng perpenicular line at . From D, raw D E parliel to B C, raw B E parliel to A D, oin E A, then E D is the ngle of the oards. From as a centre, vith C B as raius, describe rc cutting A D, roduced in F; oin E F; D E F the angle o mitre the oards cut as before directed. QUERIST ight look in back numbers again, however; see lso Vol. I., pages 173, 414, and 731.—B. A. B.



Bevels for Dovetailing—A B C is the Angle of Side Elevation; A E D, Angle to cut the Boards; E F D, Angle to mitre Corners.

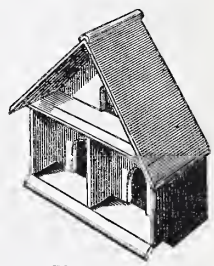
**Observatory Hive.**—J. J. (*Kidderminster*).—f course you know that an observatory hive is one n which the operations of the bees can be watched hrough some transparent medium, usually glass. Ve must, therefore, have glass sides to the hive; utit would not do to have the light always entering, onsequently shutters are provided for darkening p tbe hive, and for preserving the heat which the lass is only too prone to dissipate. It would not do o bave more than one comb in thickness, as, if here were more, the seeret operations of the hive vould be carried on between them beyond the bservation of the owner. The number of combs vhich the hive is to contain is a matter for conideration also. One, three, or six standard frames re usually found in observatory hives. In the igure I give an elevation of a three-comb observaory hive of simple construction, which I designed or my own use. The important parts are the side ieces, A, A, which ought to be very accurately cut o the dimensions shown. They are 2 ft. 5¾ in. long, in. wide, and 1⅝ in. or 1½ in. slaek thick. When hey have been planed true and square, they are to e clamped together, and the reeesses cut out where sbown. Then the pieces B and C should be prepared; they are 1 in. thick, 1⅝ in. wide, and long enough to keep the insides of A, A, 14½ in. apart, and the inside surfaces of the recesses 17 in. apart. To do this, the recesses must be 1½ in. deep, as shown in the figure. These four pieces must now be firmly screwed together out of winding, so that they will be flat and square, and this is the most important part of the work. Both sides of the frame thus constructed will now be found to be flat and uniform; and if not, the plane should be brought to bear until things are right. As the glass will lie against the outside surfaces of this frame, they should be covered either with cloth or wasb-leather glued neatly on. The sides, I, I, and bottom, D, may now be put on. They are 3½ in. wide and about I in. thick, but the thickness does not mueh matter. As, however, they are intended for the outsides of the hive, tbey must be nicely finished. They are attached to the frame already made with brass screws, and if the corners are well done they will be a most important factor in strengthening tbe



Observatory Hive.

entire strueture. The top, K, is 5 in. or 6 in. wide, and long enough to project about an inch over the sides, I, I. It is sloped from the centre towards the front and back like a roof, and the ends are also chamfered. Two sheets of good glass (either plate or flatted crown preferably), 2 ft. 5¾ in. by 1 ft. 6½ in., must now be procured, and tbey can be laid one at each side of the inner frame, and bedding against the cloth or leather, will exclude all draughts from the bees inside. One of the glasses can be fastened permanently in place with small strips of wood tacked on outside; for the other we must put one strip along the bottom, and sink a little button into the thickness of the top to secure it above. A pair of doors must now be made to fit over the glasses. They should be panelled, and the sides next the glasses padded softly with hair or feathers, and covered with cloth. This will check the tendency of the glass to cool the inside. I must not forget to mention that little strips of tin must be tacked at the edges of tbe recesses to support tbe frames, which should be either of Abbot's broad shoulder type, or provided with metal cnds, so that the space at each side will be uniform. With regard to an entrance, if tbe hive is meant to be stationary, a tunnel could easily be cut through one end. These hives, however, are often made to revolve; and when so, far more work is necessary. A vertical tube must be glued to C, D, and revolve on the washer. E, and the base-board, F. If this tube is of metal, the lower end could be slightly opened to prevent the hive from being lifted off by mistake, but I prefer a bit of elder-wood from which the pith has been removed, and in such a case it is necessary to leave the lower end rather thicker than the top, and to insert the tube from the bottom. A tunnel will, in every case, lead from the lower end of the tube to the open air, and a small alighting board should be attached. In ease you wish for a unicomb hive, you may omit the two upper storeys, and if you require one to contain six frames, make it twiee the length. As I said at the beginning, tbe important part is the frame, A B A C, and, if necessary, sheets of glass could be tied to the sides of this with string, and a few bags and tarpaulin tied round the lot to keep in the heat; but I think you are too worthy an apiarist to adopt this method. The movable glass should have its edges slightly smeared with vaseline to prevent propolisation. I shall be most happy to help you any further, and hope you will succeed.—APIS.

**Pigeon House.**—R. V. B. (*Peckham*).—I give a sketch of above suitable for three pairs of birds. It is very simple, and all you require to make it is about 20 ft. of ¾ in. by 9 in. yellow boarding, 12 ft. of ¾ in. yellow matchlining, and a few nails. I should eover the roof with a piece of old linoleum or floor-cloth, which can be painted with the rest. It should be fixed on a sunny wall. You will notice that the floor or bottom of nests is lower than the flying board, for the purpose of keeping the stuff, etc., from getting all over the place. I hope this will meet your requirements.—E. D.



Pigeon House.

**Bending Tubes.**—J. S. (*London*).—I find, on making inquiries, that there is no macbine at present made for bending taper tubes. I fail to see why it does not pay to bend them by hand over a mandrel. Do you mean a taper bick iron? That is what I should use, and turn three at once half-round, and finish singly—the same as we make saucepan handles; and they are made quick enough for anything.—R. A.

**Fixing Old Coins in Frame.**—C. T. (*Boston*).—The coins would probably remain in place if fixed with Le Page's liquid carriage glue, and much might be done in way of supporting them by fitting the frame with a sheet of millboard pierced with holes of the size of the coins, which would thus rest in sockets. As a coin collector, however, I by no means advise C. T. to fasten his coins with cement of any kind. The reverse of a coin is often as interesting as the obverse—sometimes more so—and both sbould be open to inspection. If he is bent on exhibiting his coins in a picture-frame, his more rational plan will be to have a frame constructed as in the diagram—that is, witb a series of narrow sloping wooden shelves, each shelf wide enough for a single row of his largest coins. Along each of these shelves he will glue a strip of millboard pierced with holes to hold the coins, which will thus keep in place witbout any cement. The glass front of the frame will, of course, be made to open and shut, and *lock*.—S. W.

Frame for Coins.

**Pocket Accumulator.**—J. B. (*Bradford*).—Low-priced pocket accumulators are not obtainable. Skilled labour must be employed in making them, and this labour must have its reward. The lowest price is half a guinea. The best in the market are made by Messrs. Cathcart, Peto, & Radford, 57B, Hatton Garden, London, W.C.—G. E. B.

**Brass-Work and Re-silvering.**—T. T. (*York*).—To re-silver your spoons, see the articles by Mr. Bonney on electro-plating in the present volume; and for lacquering your brass-work, you cannot do better than use one of the new substitutes for laequer sold by the Frederick Crane Chemical Co., Newhall Hill, Birmingham. These very useful specialities were noticed in "Our Guide to Good Things," No. 106, and some information as to their

use was given in "Shop," No. 107. The courteous manager of the Company, Mr. Charles Harrop, has intimated that he will send a sample bottle of any of their preparations for 1s., post free, to any reader of WORK.—R. A.

**Bench Lathe.** — B. O. (*Stoke-on-Trent*).—If I understand right, your 2¾ in. pulley works with the 24⅜ in. one. To find the speed ratio, divide 24⅜ in. by 2¾ in.; by putting both into ¼ in., you get 99 divided by 11, which is just 9 to 1: a very proper speed for small work in wood. You can calculate the other sizes yourself, but if the 4 in. pulley on mandrel works with the 5½ in. on the crank shaft, you get quite a slow speed, and can turn iron up to 1 in. or so in diameter, and brass up to 3 in. or more. Now, if you want to reckon the weight of the rim of your fly-wheel without having to weigh it, you must find the number of cubic inches it contains of cast iron, and multiply that by ·26, and that will give you the weight of the iron in lbs., because a cubic inch of cast iron weighs ·26 of a lb. Since part of your rim is of lead, which is nearly twice as heavy as iron—namely, ·41 lb. per cubic inch—you must multiply the cubic inches of lead by ·41 to find the number of lbs. For instance, take the rim of lead, which you say measures 2½ in. by 1⅝ in.; multiplying these together, you get about 4 square in. of sectional area; now, if the mean diameter of the rim is 23 in., the length is 72 in.; multiply 72 by 4, and you get 288 cubic in. in the lead rim, and this multiplied by ·41 gives 118 lbs. as the weight of the lead rim. I think 50 lbs. is heavy enough for the fly-wheel of a 3 in. bench lathe, and that yours is unnecessarily heavy, and would do for a large 6 in. lathe. Now for the treadle, which you say rises too high. The crank has a throw of 2½ in., and therefore, a stroke of 5 in. (2½ in. is a more usual crank); also it is 11 in. from treadle bearing to treadle hook, and 22⅜ in. from treadle bearing to foot-board. In that case the foot-board will have a motion up and down of 10 in.—that is, twice the throw of the crank—because the treadle is a lever having one arm twice as long as the other. Now, if you carry the treadle bearing 11 in. further back, as you propose, then the arms of the lever will be 22 in. to 33 in.: about, say, 2 to 3. To get the movement of the foot-board, divide 5 by 2 and multiply by 3, so: $5 \times \frac{3}{2} = \frac{15}{2} = 7\frac{1}{2}$ in., which is the distance the foot will rise and fall, which I think about right for a small lathe; for a large lathe, where you want more power, I think 9 in. not too much. You could have easily found out what the movement of the foot would be without any figures if you had drawn out the treadle full size. Now for the axle bearings. You can have the axle hung on points, but it might be better to have the bearings fitted with new brasses, as your wheel is so heavy. If you wish to run on points, the pointed screws should be of steel, perfectly hard, and of an angle of about 60°; they may pass through 1½ in. or 2½ in. of cast iron, and be secured with a lock-nut. The iron crank-shaft may be drilled up an inch or so with a ⅜ in. hole at both ends, and a hard steel plug driven into each; these steel plugs to be drilled right through the centre with a ⅛ in. hole, and then deeply countersunk to exactly the same angle as the point of the screws, deep enough to hold nearly all the point, and even then the bearing is small enough; the hole in the plug forms a reservoir for oil. Vol. II. begins with No. 53.—F. A. M.

**Violin Articles.** — J. B. C. (*Liverpool*). — The articles on the Violin commenced in No. 105 of WORK.

**Embossed Letterings** —L. S. (*West Hartlepool*). —If only an odd job, Messrs. Bentley & Sons, Embossers, Norfolk Street, Sheffield, would be a likely firm to address on the subject, sending to them the article to be embossed. On the other hand, if you require a large number of the embossed articles, your best plan will be to write to a die-sinker for an estimate for the die, and the price for stamping a given number, including metal. Mr. Wise, Tenby Street, Birmingham, or Mr. Pashley, Edward Street, Sheffield, will, no doubt, furnish estimates on application, enclosing stamped directed envelope for reply.—N. M.

**Moulds for Carbon Plates.**—S. H. (*Rochdale*). —I cannot think of any easier method than to make patterns of the moulds to the size of carbon plates or rods desired, and have the moulds made in cast iron. Each mould should be made in two halves, with the joints grooved and tongued. The two parts of the mould will be held together by a wrought-iron ring or clamp slipping on over both parts, and tightened with iron wedges. The mould will be in the form of a shallow box, open at one end. At this open end the paste must be pressed in and rammed tight, then a piece of iron must be fitted into the end to form a cover, and this must be secured by a clamp. All joints should be closely fitted, to prevent the syrup from squeezing out, but it is not necessary to attempt making them air-tight. —G. B.

**Combination Bench and Tool Chest.** — W. H. W. (*Great Yarmouth*).—Why not submit particulars of this through Section I. of "Shop"?

**Lithography: Re-transfer and Plate Papers.** —A. R. (*Blackburn*).—These papers are prepared as follows: Make a size by boiling parchment strippings, which when cold should be of the consistency of a *firm* jelly (gelatine is sometimes used instead). Grind flake-white in water, mix it with the size (which must first be warmed), and pass the mixture through a sieve. (*Note:* the proportion of flake-white must vary according to the uses for which the paper is intended; too much will prevent the pen working well upon it if *writing* be wanted.) Coat the paper twice with the size, letting the first coat dry before the second is applied. For this part of the process use a flat brush, and work the size *up* and *down*, but do not cross the strokes. Gamboge or rose-pink is added to the size simply to enable the lithotransferrer to see at a glance which side of the paper is sized. This size is suitable for plate paper, re-transfer paper, and writing transfer paper, the only difference being a variation in the strength of the size, quantity of flake-white, and weight of paper; plate paper is generally 48 lbs., re-transfer 32 lbs., and writing 24 lbs. The two last have to be rolled after sizing, but plate paper is left unrolled. After each coat of size the sheets should be hung across a line to dry. If, as would appear to be the case, A. R. is an amateur lithographer, he might find it to his advantage to get Mr. W. D. Richmond's "Grammar of Lithography," published by Wyman & Sons, Great Queen Street, Lincoln's Inn Fields, W.C. We should add that we very much question whether it can pay A. R., or anyone similarly situated, to prepare his own papers.—S. W.

**Timber.**—G. (*London*).—(1) The following oaks are imported into London: American, Dantzic, Trieste, Stettin, Memel, and Finne. (2) The American logs are the widest, and can be had from 16 in. to 24 in. in size. The others do not run wider than 14 in., usually from 10 in. to 14 in. (3) Any of these oaks can be obtained at most timber-yards, especially in the East End. (4) It is generally sold by the load of 50 cubic feet. (5) The prices are about as follows: American, £7 10s. to £8 10s.; Dantzic, £3 to £5; the others run from £4 to £7, according to size and quality. (6) Sawing would cost about 1d. per foot super. (7) A large quantity of foreign oak is unloaded in the Surrey Commercial Docks. (8) No doubt American would answer your purpose best, but neither of them are equal in "figure" or durability to English oak.—A. J. H.

## III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Upholstery.**—T. C. (*Belfast*) writes:—"I shall be obliged to anyone who will tell me how to cut the cloth to cover a couch or sofa to have it neat and without wrinkles. I am not able to cut it properly."

**Xylonite.**—L. S. (*Beaverstown*) writes:—"Will any reader kindly tell me, through the medium of 'Shop,' where I can procure xylonite in small quantities? I wrote to the British Xylonite Co. for as much as would veneer the front of the cabinet, the design of which was published in No. 1 of WORK. I wanted it in black and white to inlay, but they replied that they do not cut less than a gross of pieces."

**Glacial Decorations.**—J. H. (*Salford*) writes:—"Will any kind reader of WORK kindly oblige by informing me how to remove glacial decorations?"

**Compound Engine.**—PUZZLED writes:—"Would any of you engineers who take in WORK help me? How is the steam exhausted from the high-pressure cylinder so that it does not exert a back pressure equal to the pressure it exerts on the low-pressure piston? I have asked dozens of people, and the only answer you get is, 'Yes, I wonder how it is?' What size ought the receiver to be—that is, the pipe from high-pressure cylinder exhaust to low-pressure cylinder steam-chest? Also, how do you find out what size to make low-pressure cylinder? I am sure a good answer to this would interest many."

**Bread Machines.**—JEAN writes:—"Will anyone kindly tell me, through the pages of 'Shop,' where bread-dough kneading machines are made? Address and prices wanted."

**Door-Mats.**—JEAN writes:—"Will any of your readers kindly tell me how the common brown door-mats are made?"

**Root's Blower or Blast Fan.** — F. W. B. (*Huddersfield*) writes:—"Will anyone kindly give the name and address where I could buy a set of castings for a small Root's rotary blower, or a small blast fan, say, 4 in. to 6 in. diameter, suitable for brazing with small gas blowpipe?"

## IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Wax.**—L. S. L. (*No Address*) writes, in reply to CARVER (see page 206, No. 117):—"I find the following recipe recommended, but do not know its value myself: Equal parts of beeswax, lead plaster, olive oil, and yellow resin; add whiting sufficient to form paste; mix well, and roll into sticks. The *exact* proportions will, I fancy, be modified to some extent by the temperature."

**Turned Balusters.**—J. E. P. (*Accrington*) writes, in reply to F. E. H. (*Lancaster*) (see page 158, No. 114):—"You could get stone balusters turned at C. Pollard & Sons, Meadow Tap, Accrington."

**Band-Sawing Machine.** — CHOPSTICK writes, in reply to BON ACCORD (see page 190, No. 116):—"I will describe a machine made of wood which I have used for many months, and have cut heavy wheel timber on it. It is too large a subject for 'Shop,' but if the Editor gives me permission, I will send the paper on at once."—[You may send in the paper on approval.—ED.]

## V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—AN OLD EDISONIAN; PLUMBER, F. K. B. (*London, E.*); W. B. (*Brunteliffe*); T. G. W. (*Clapham*); W. G. C. (*Bradford*); A. M. (*Liverpool*); G. A. B. (*Normanton*); VULCAN; W. W. (*Hough*); S. S. (*Salford*); R. A. (*Kingston-on-Thames*); CONSTANT READER; W. G.; HUGH; H. H. P.; CURIOUS; T. L. (*Riseholme*); MIKADO; J. G. S. (*Stockton*); W. A. S. (*Bolsterstone*); J. M. D. (*Glasgow*); G. M. (*Reading*); LITHO PRINTER; J. G. L. (*Sheffield*); FRET MACHINE; GANELON; T. W. C. (*Springfield*); W. W. (*Caverton*).

## AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their Improved Eclipse Cameras and Outfits, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above: also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra.

These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.**, post free.

*A Wholesale Dealer's Stock-in-Trade at about Half-Price.*

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

**J. H. SKINNER & CO., Manufacturers, W Department, EAST DEREHAM.**

## THE NAVAL EXHIBITION.

Crown 8vo, price *1s.*, post free.

### All About the Royal Navy.

By W. LAIRD CLOWES. Illustrated.

"Of the many books to which the Naval Exhibition has already given rise Mr. W. Laird Clowes's 'All About the Royal Navy' (Cassell) is the best. . . . He discusses all sorts of topics, from the duties and stations of the Royal Navy to guns and torpedoes; from describing battle-ships he proceeds, in a graphic and animated passage, to imagine our next naval fight, and in an appendix he explains how to enter the Navy."—*Daily Chronicle.*

CASSELL'S LIBRARY EDITION OF

### Southey's Life of Nelson

contains Eight Full-page Illustrations. Extra crown 8vo, cloth, 3s. 6d.

"Printed in bold, clear type, on paper of unusually good quality, with wide margins to the page, and is illustrated with several well-executed woodcuts. This is an ideal edition for school prizes and for gifts to boys."—*Daily Chronicle.*

### Southey's Life of Nelson

has been published as a volume of the NEW ISSUE of **Cassell's National Library,** price 3d., post free, 4d.; or cloth, 6d., post free, 7½d.

"The book is a marvel of cheapness, being well printed and compact."—*Admiralty and Horse Guards' Gazette.*

"Southey's is far and away the best biography of the great admiral, and the present issue will bring it within the reach of the poorest boy that can appreciate the story of a daring life."—*Norwich Argus.*

SECOND EDITION, *1s.*; post free, *1s. 2d.*

### In a Conning Tower;

or, How I Took H.M.S. "Majestic" into Action. A Story of Modern Ironclad Warfare. By H. O. ARNOLD-FORSTER. With Original Illustrations by W. H. OVEREND.

"A graphic and most vivid description. . . . Mr. Overend's illustrations are as vivid in their way and as accurate as Mr. Arnold-Forster's description. We can scarcely give them higher praise."—*Times.*

Fretwork Outfits, 1s. 4d., 2s. 6d., 3s. 6d., and 5s. 6d. each.

*Sets of Twelve Best Carving Tools, with Boxwood Handles, 10s. free.*

All Materials and Tools supplied for Fretwork, Carving, Picture Framing, Brass, Leather, and Burnt Wood Work.

Our Catalogue, acknowledged the most complete, with 1,000 Illustrations, free for six stamps.

**RIZALINE,** for Painting or Fretwork. Sheets, 20 by 15 inches, 2s. 6d. each.

**HARGER BROS., Settle, Yorks.**

PRINTED AND PUBLISHED BY CASSELL & COMPANY, LIMITED, LA BELLE SAUVAGE, LONDON, E.C.

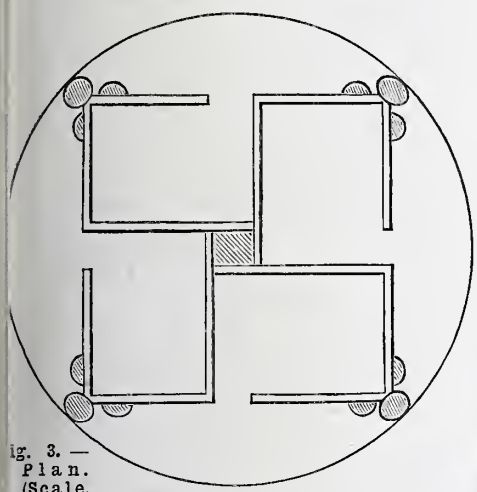
# WORK

## An Illustrated Magazine of Practice and Theory

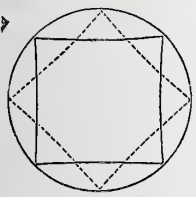
FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

[*All Rights reserved.*]

VOL. III.—No. 123.] SATURDAY, JULY 25, 1891. [PRICE ONE PENNY.



ig. 3. — Plan. (Scale, 1½ in. to 1 ft.)



ig. 2.—Section of Pole. (Scale, 2 in. to 1 ft.)

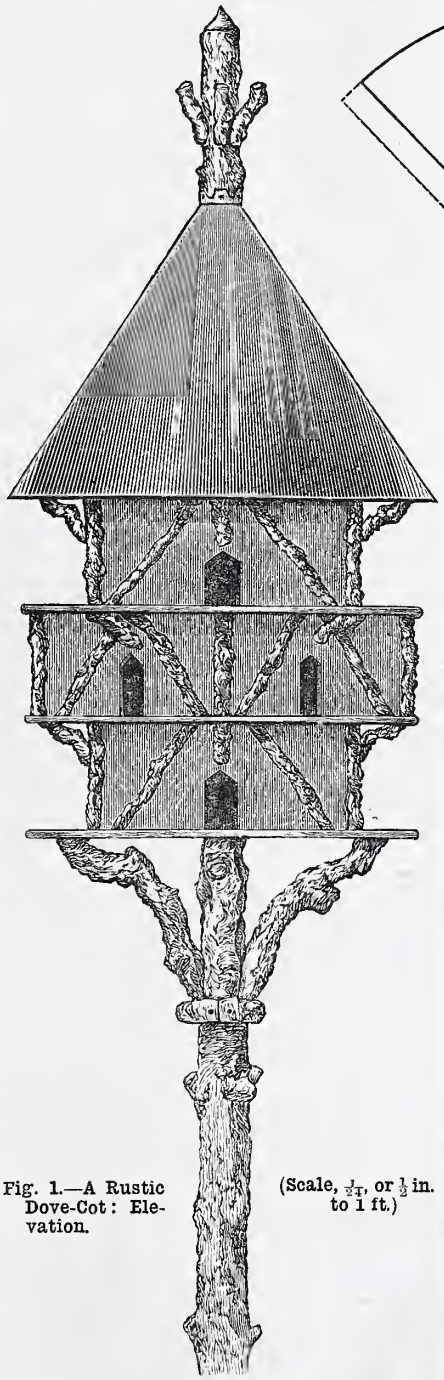


Fig. 1.—A Rustic Dove-Cot: Elevation. (Scale, $\frac{1}{24}$, or $\frac{1}{2}$ in. to 1 ft.)

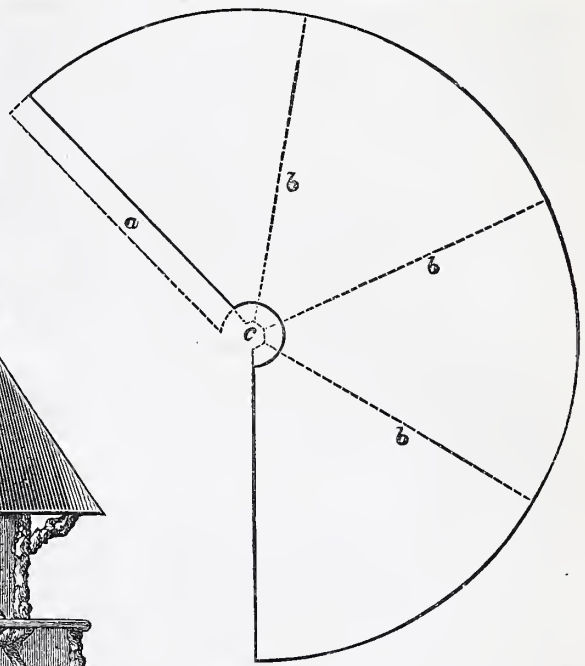

Fig. 4.—Setting out Metal Roof. (Scale, ½ in. to 1 ft.)

## A RUSTIC DOVE-COT FOR THE GARDEN.

BY ARTHUR YORKE.

THE POLE DOVE-COT — THE WOODWORK — THE METAL ROOF.

*The Pole Dove-Cot.*—A pigeon-house of this kind has, it must be owned, its disadvantages: except for the hardier kinds of birds, it is apt to be too cold in winter, and may be too hot in summer. But there are situations in which it alone is available, and to those who keep pigeons, not for "the fancy" nor for profit, but for the pleasure of their company, none other is often so desirable, none other so well admits of being placed before a window, and thus to give the owner the full enjoyment of watching his pets; none other can be made so ornamental; nor, indeed, is any other so safe from the worst enemies of pigeons—cats and rats.

As it is in a garden that a dove-cot of this kind will most frequently be placed, it will be well to keep it in harmony with its surroundings, and unless the garden is very small or very formal, this, perhaps, will best be done by carrying it out to a great extent on rustic lines.

I say to "a great extent," and not altogether, for the actual boxes ought always to be neatly made of planed wood, and painted within and without. Pigeons are subject to parasitical vermin of more kinds than one, and all arrangements for housing them should therefore be made in such a manner as will allow of thorough cleansing.

In the design before us this consideration has been kept in view. It contains twelve boxes—and good roomy ones—each being 18 in. by 12 in., and 13 in. high.

The illustrations are drawn to scale as named in the inscriptions to the diagrams, which see. By working out the design on a smaller scale, it might very well be adapted as a nesting-place for starlings or other wild birds. The starling gladly avails itself of any home provided for it, and no bird wages more inveterate war on grub pests than he. We in England treat him with too scanty courtesy; in some countries, as in Russia, the starling-box is a recognised institution in a garden.

*Woodwork of the Dove-Cot.*—The first and most important matter will be to provide a larch or other fir pole, of which the diameter will average, say, some 6 in. Its length may be varied to taste; some prefer the dove-cot higher, some lower, but few, we presume, will care to have its bottom less than 8 ft. or 10 ft. from the ground; to this must be added 2½ ft. or 3 ft. to be firmly planted in the earth, 6½ ft. for the height of boxes and roof, and 2 ft. for the finial above.

At the point marked off on the pole for the bottom of the cot, we make cuts with the saw on the four sides, and again 15 in. higher, and chip away the wood so as to leave our pole 4 in. square. This is the space for our lowest tier of boxes. To make a space for our middle tier, we treat the pole in the same manner for the next 14 in., only we make the corners of this second space to come opposite to the middles of the sides of the space below. Fig. 2 is a section of the pole illustrating this: the circle marks the original outline of the pole,

the black lines show the space for the lowest tier, and the dotted lines that for the middle one. The upper tier will occupy another 14 in., and this will be a repetition of that prepared for the lowest.

A reference to the plan of one of the tiers (Fig. 4) will show the use made of the squared spaces; one of the partitions which divide the boxes is nailed to each side, whilst the boards which form the outer walls are nailed to the ends of these partitions. For the comfort of the birds, 1 in. stuff should be used for all these pieces: it will be none too thick when planed. For the divisions between the tiers—floors and ceilings—which will be round discs of board 4 ft. in diameter, the best job will perhaps be made by screwing together at right angles two layers of ½ in. match-boarding. The disc for the top, it will be seen, is larger by 6 in. than the others, that it may give overhanging eaves.

In front of each cell we get a good space, 9 in. wide, for the birds to disport themselves, as they delight in doing; and each of these platforms is completely cut off from the rest, which, for the avoidance of quarrels between the cocks, is held to be an essential point. Our arrangement also places the entrance to each cell towards its end, not its middle, which is considered desirable, as giving privacy to the nest.

Having their bases on the disc of board which covers the top tier of boxes, and their perpendiculars against the pole, which is shaved level to receive them, we nail four triangular pieces of 1 in. board to serve as rafters for the metal roof. We give to these pieces a perpendicular height of 3 ft. It will be a good plan to fill the places between them and the metal covering with sawdust, which, being a non-conductor of heat, will tend to equalise the temperature of the cells.

The few pieces of rough wood used as rustic decoration are so plainly figured as to need no verbal description, but before they are fixed in place the planed work should receive a couple of coats of paint. In the interests of cleanliness it is recommended that the insides of the cells should be painted white; the outsides will look best coloured of such a brown as will go well with the bark of the rustic-work.

*The Metal Roof.*—It is proposed that this should be of zinc or sheet-iron. For my own part, I should prefer black (ungalvanised) iron, as on this paint will stand best. Setting out a conical roof is not a difficult matter. We strike a circle of which the radius equals the length of our rafters, or rather, what a rafter would be if they formed a complete cone instead of terminating at the side of the pole. Of the disc thus marked out we measure so much on the circumference as equals the length of our eaves, and from the ends of the portion measured draw lines to the centre. This gives us the piece of metal we require, except that we shall need a trifle more to lap over and nail down. In Fig. 4, drawn to a ½ in. scale, we have such a piece of metal as will be required for the roof before us. The dotted lines at *a* show the over-lap, which is nailed through the corresponding edges of the metal to one of the rafters; and at *b*, *b*, *b* are lines which show where the nails into the other three rafters will pass. At *c* is seen the size of the opening to admit the passage of the pole. Strong copper tacks are best for fixing on the metal cover, and if the latter is of zinc a better job will be made by soldering the joint. There is no reason why the covering should not be cut from two or four pieces of metal, if it is found more convenient to do so.

A good colour for the roof—one which will go well with the body of the dove-cot and rustic-work—will be a dark sage green.

## ENGINE AND BOILER MANAGEMENT.

BY M. POWIS BALE, M.INST.M.E., A.M.INST.C.E.,

*Author of "A Handbook for Steam Users," "Wood-working Machinery," "Stone-working Machinery," "Pumps and Pumping," etc.*

### Rules for Engine Drivers and Boiler Attendants.

Firing the Boiler—Prevention of Smoke—Fire-Bars—Working Portable Engines, etc.—Working Traction Engines—Working Engines and Boilers in Frosty Weather—Blowing off or Emptying Steam Boiler—Cleaning Boiler—Engine and Boiler out of Use—Stopping Engine—Banking Fires for the Night—A Good Engine Driver and Boiler Attendant.

In continuing my subject I had better point out that Rules 1—18 have been laid down and explained in a previous paper, to be found in page 229, *et seq.*

19. *Firing the Boiler.*—Use good fuel if possible. Do not put coal on in large pieces, but break it to about the size of your fist. Do not put on a large quantity of fuel at one time, but fire little and often. If the fire burns unequally or into holes, level it and fill up the vacant spaces. If anything, the fire should be rather thinner in the centre than at the sides of the fire-box. Do not let the fire get low before a fresh supply of fuel is added; keep the furnace door closed unless there is a surplus of steam. Be careful in regulating the draught in the fire-box or furnace to suit the fuel being consumed. We recommend, wherever possible, the use of an automatic steam damper. A good supply of air promotes combustion, and tends to prevent smoke. In Cornish or Lancashire boilers, begin to charge the furnace at the bridge, and keep firing to within a few inches of the dead-plate. Excessive draught should be avoided, as the heat is carried rapidly away, and sufficient time is not given for the combustion of the various gases. Coke requires a more rapid draught than coak The flame of the fire should never come in direct contact with the boiler-plate above the water-line. The flame should never be allowed to impinge constantly on one spot, either above or below the water-line. The fire should never be collected in a heap in the middle of the grate, as it allows cold air to rise through the bars all round it and strike against the boiler-plates.

Keep ash-pit and fire-bars clean, and free from clinkers and ashes. Do not slack the ashes in the pit, but remove them at once. If it is necessary to use wood as fuel, it should be dry, and be reduced to pieces, say, 12 in. long. For, say, the last half-hour before finishing work, do not put any more fuel on the fire, and raise the water-level in the boiler, so that the boiler may cool down gradually. With some kind of coal it is necessary to clean the grate often, to prevent the fire becoming choked with clinkers, etc.; to clean the front part of the grate, push the fire well back, and use the slicer and clinker hook freely; to clean the back of the grate, bring the fire forward, and pull the clinkers over it. When this is finished, spread the fire evenly again, and put on a moderate supply of coal. The fire should not be allowed to burn too low before cleaning, or the steam pressure may drop considerably, or the fire go out. Before cleaning, see that there is a good supply of water in the boiler, and partly close the dampers whilst cleaning. Remember that scale in the boiler and choked tubes often render it necessary to force the fire to make up the loss accruing therefrom. Fire as rapidly as may be, and do not keep the furnace door open longer than is necessary. Whenever possible, the damper should be kept closed when the furnace door is open, and *vice versâ*. A bright, incandescent fire will reflect a bright light into the ash-pit. If the ash-pit is dark, there is probably an accumulation of ashes or clinkers that require moving. A good fireman will see that no useful cinders are thrown away with the ashes. If a forced draught is used, thicker fires than those already mentioned may be employed, but care should be taken that a forced draught is not used when the grate is partially uncovered, or leaky tubes or seams will soon be the result.

20. *Prevention of Smoke.*—The prevention of smoke is very largely a matter of careful, regular, and even firing, and the admission of exactly the right quantity of air into the fire-box. Furnaces constructed of ample area of cubic capacity will burn smoke better than those that are confined. A good supply of hot air admitted from the bridge of the furnace aids combustion. Use a furnace door through which the supply of air may be easily regulated, so as to spread, as it were, an even sheet of air over the surface of the fire. Alternate firing on each side of the furnace has a tendency to prevent smoke, but with most coals the author can recommend the following plan as a decidedly good and effective one for aiding combustion and preventing smoke. Supposing the fire to be in an incandescent state, and it is necessary to put on more fuel; instead of throwing the coal on in the usual way, push back the fire from the front part of the fire-grate on to that behind, nearer the bridge, leaving the front of the grate bare. Now charge the front part of the fire-box with fresh coal; this will gradually coke, and the various gases, etc., which form smoke will be liberated at a slow rate, and give time for the air passing up through the fire-bars to become heated and mingle with them, thus promoting tolerably perfect combustion. With this plan, with ordinary steam coal and tolerably open fire-bars, a sufficiency of air will pass up through the fire-bars in the front of the grate to consume the gases, and large volumes of smoke need never be made, as is the case when great quantities of fuel are thrown on to a hot fire. The reason of this is that in this latter case, owing to the incandescent fire acting quickly on the coals, the combustible gases or hydro-carbon are so rapidly released that there is not a sufficiency of air admitted to the fire-box and heated fast enough for it to combine with and consume the liberated gases; hence the production of free carbon or smoke. This coking system of firing should be performed at regular intervals, and only moderate supplies of fuel be put on at one time.*

In cases of urgency smoke may be "whitewashed" by turning the exhaust or a jet of steam into the base of the chimney-stack. Bear in mind, a blue flame shows imperfect, and a white one tolerably perfect combustion.

* "A Handbook for Steam Users." M. Powis Bale (Longmans & Co.).

21. *Fire-Bars.*—As the bars are burnt out, renew them; do not wait till the whole set is worn out. Allow a good current of air to enter through the ash-pit and fire-bars, for the latter may become over-heated—specially with some kinds of fuel—and burnt out. If the fire burns sluggish, it may be from insufficiency of draught, or the fire-bars may not be provided with sufficient air spaces, and these, getting choked, require constant attention to prevent the bars warping or burning. Keep the ash-pit and fire-bars clean and free from clinkers and ashes. Do not allow an accumulation of hot ashes in the ash-pan or pit, as they have a tendency to twist the fire-bars. In some cases, with coal given to form much clinkers, etc., rocking fire-bars may be used with advantage. Do not take more time than is necessary in cleaning bars, leave the damper open, and when the coal is pushed back, do not let a fierce fire impinge against one place in the fire-box for any length of time. Hard steam coal requires less air space between the bars than free flaming bituminous coal. Never throw water into a warm fire-box to loosen ashes or clinkers by contraction.

22. *Working Portable Engines, etc.*—In the case of portable engines, place the driving wheel exactly in a line with the pulley of the machine to be driven. Fix the smoke-box slightly higher than the fire-box end. Wedge up the wheels, and see that the engine does not rock in working. Always keep about 2 in. of water in the gauge-glass, and blow off occasionally through the glass to see that the ways are clear. Clean the boiler periodically right through, and if the water is bad, remove the hand-hole in the fire-box, and carefully remove all sediment over the fire. An accumulation of sediment is the chief reason for burnt boiler-plates. On finishing work, a great deal of scum and dirt may be got rid of by blowing off at a low pressure, if possible, when the engine is being removed to a fresh job.

23. *Working Traction Engines.*—As regards the working of traction engines, the rules given above will apply equally well to those as to most other types of engines and boilers; in addition, however, the driver of a traction engine should bear the following points in mind:—(1) Keep a good supply of water in the tank. (2) Disconnect the traction gear, and start the engine under a moderate head of steam—say, 25 lbs. pressure—to see that the pump and all the working parts are in order. (3) Carefully oil all bearings, and grease the teeth of the various wheels. (4) For travelling, get steam up to about 75 lbs. pressure. (5) When going down a hill, the gauge-glass should show 1 in. of water; when going up, about 4 in. (6) In going down hill, lock the hind wheels of any vehicle being drawn; use the reversing lever, both for shutting off steam and for checking the momentum of the engine, by admitting steam to the reverse side of the pistons.

24. *Working Engines and Boilers in Frosty Weather.*—When working in frosty weather, the following additional precautions are advisable:—(1) Close the tap between the boiler and the water-gauge glass when the boiler is stopped for the night, and let the water out of the glass. (2) Leave the cylinder-cocks open to drain off the condensed water, also the jacket-cocks if the cylinder is jacketed. (3) Examine the pump and valves and supply pipes carefully before starting work; if frozen, pour hot water on them till the ice is thoroughly melted. (4) In very frosty weather have the fly-wheel of the engine barred or turned round by hand a few times, in case of ice being in the cylinder. (5) Thoroughly warm the cylinder before starting; carefully try the different cocks, and pour hot water on them if stiff. (6) See to the cylinder and other lubrication. Kerosene mixed with oil will prevent it freezing. (7) Leave all drain-cocks in pipes, etc., open; the water in boiler may be prevented freezing by banking the fire.

25. *Blowing Off or Emptying Steam Boiler.*—If the boiler is emptied under pressure—a practice I do not usually recommend—the pressure should not exceed, say, 10 lbs. per square inch. It is better to let the damper be open and blow off through the safety-valve, at the same time adding fresh cold water to mix with that in boiler if early cooling is necessary. On no account throw cold water on hot plates. The cooling should be gradual and general; it is better not to let the water out of the boiler till the boiler-plates and boiler-seatings are cool. Never admit cold water when the boiler is empty and warm. One disadvantage of blowing off under pressure is that the boiler-plates and brick-work, being left hot, have a tendency to harden any scale or incrustation that may be adhering to them. Before removing man-hole or other covers, lift the safety-valve, and make sure that there is no steam in the boiler; neglect of this precaution has caused accidents.

26. *Cleaning the Boiler.*—To clean the boiler, remove all the covers of the man-holes; scrape, or, if there is much hard incrustation, chip the interior surface, thoroughly loosening and removing all sediment and dirt. Pass a quantity of clean water through the man-hole. Examine and clean all feed-water and other pipes periodically; remove and scrape fusible plug, and renew if necessary. Keep all flues or tubes thoroughly clean and free from soot, etc. Examine all cocks and fittings, and see that they are in order and free from leakage. Examine the flues, and see that the boiler-seatings are dry, and that there is no leakage either from the seams or from the roof. Tubular boiler tubes should be swept once a day, or twice if the fuel be bad. This can be readily done with a jet of steam.

27. *Engine and Boiler out of Use.*—When a boiler is out of use for a time, it should be entirely emptied of water, carefully dried, and painted with an oxide paint inside and out. Several boxes of quicklime for absorbing moisture should be put inside the boiler, and if on inspection it is found much slaked, it should be renewed. Coat the bright parts of the engine with a mixture of white lead and boiled tallow: say, 2 lbs. of the former and 6 lbs. of the latter; or, if preferred, a mixture of boiled oil and turps may be used.

If an engine has been standing some time, it should be thoroughly overhauled and cleaned over with paraffin to remove dirt, and well lubricated. Before starting, the engine should be well blown through with steam to warm the cylinder and try the joints, which may require renewing.

28. *Stopping Engine.*—In stopping the engine, turn off the steam gradually, and not suddenly, as this latter practice has been known to start joints or split pipes from the shock arising from the sudden stoppage of the flow of steam. Unless a barring engine is used, care should be taken that large engines are allowed to stop on the dead-centre, or they will give considerable trouble in being levered round by hand. Large establishments should be so arranged that instant communication can—in case of accident—be made with the engine driver. An electrical apparatus is now in use by which the engine can be instantly stopped from any desired point.

29. *Banking Fires for the Night.*—Although there is some little danger attached to the practice of banking fires, in a series of boilers it saves a great amount of trouble, and is generally resorted to. The following precautions should, however, be observed: (1) Put the safety-valves to blow off at a low pressure—say, 10 lbs. (2) Leave the furnace doors open. (3) Close the dampers and ash-pan lids or ash-pit doors. (4) See that each boiler has a full supply of water and the float is in order.

A good plan in banking is to partly clear the front of the fire-bars and push the fire into a gradual bank at the back, making it as solid and free from air spaces as may be; then cover with wet ashes and coal-dust mixed, to a depth of, say, 6 in. Arrange the admission of air so that there is just sufficient to keep the fire alight, and nothing more. It may be added that judicious banking of a fire is less injurious to a boiler than the constant lighting up and drawing the fire out, as the extremes of expansion and contraction are done away with. It is somewhat difficult and risky to attempt to bank fires in tubular boilers.

30. *A Good Engine Driver and Boiler Attendant.*—The greatest factor in the making of a clever engine driver and boiler attendant is regularity. A good man will keep up an even and regular supply of fire, water, and steam the whole day through, whilst a careless or inefficient man will have steam blowing off one hour and a pressure barely sufficient for the work the next. An incompetent attendant is dear at any price. To test accurately the performance of the engine under his charge, the skilled engine driver should be capable of working the indicator and taking diagrams; this work, however, I am afraid at present is relegated to those higher in authority, but there is no reason why a fairly-educated man should not do it, as several plain and practical treatises are published on the subject.

## WIRE-WORK IN ALL ITS BRANCHES.

BY JAMES SCOTT.

### Lacing—A Shuttle—Splicing—Cutting Up.

"Lacing" is the technical term used by wire-workers for the operation of securing wires to each other continuously at their various junctions. Mr. Frank Hinds, in Work, Vol. II., No. 54, page 22, shows in a very distinct manner a method of thus binding the different wires, and I will ask my readers to refer to his article upon Bird-cages in the number alluded to above, as affording additional explanation to the few remarks I am about to make.

In beginning to lace a certain part of any work, the end of the binding or lacing wire should be tied in place, if there is no possibility of otherwise fastening it to obtain the necessary security. The work is generally proceeded with from left to right if the work is horizontal, and from bottom to top if vertical.

In Fig. 53 it is supposed that the lacing wire is bent as shown in Fig. 46 (page 244); and if the reader will imagine that he can see through what is intended to represent the straight wires in Fig. 51, the parts indicated A, A, in Fig. 53 would be behind those

wires; while those marked B, B would be in front.

When lacing, the travelling end of the lacing wire is put through the second mesh, on the left-hand side, above the cross-wire, brought diagonally behind the first junction, under the bottom of the cross-wire, and out of the first mesh underneath the cross-wire; proceeding in this manner all along, by next putting the wire through the third top mesh, and out through the second lower mesh, then through the fourth and out through the third, and so on. A double stitch or lace is that shown in Figs. 54 and 55. Where there are several cross-wires to be bound, it is the usual practice to lace the first from left to right; the second, from right to left; the third, from left to right, as the first; and continue in this manner until the completion, the tendency of this being to keep the work together in a better manner.

Mr. Hinds, in his article on Bird-cages, shows a shuttle, but does not go to any length in speaking about it. Perhaps a few remarks here will prove serviceable. These articles are generally made of bone or ivory, but I see no reason why a workman should not make one in wood for his use. A and B, Fig. 57, are two pieces shaped as in plan, Fig. 56, and, with the ends (when the various pieces are finally fixed), nearly touching each other. In the middle, between the two, will be a turned piece (C, Fig. 56) screwed in place from outside the last-mentioned pieces. The wire, as perhaps can be comprehended, is wound around the cylindrical portion of the shuttle, as is cotton around a reel. By its means the hand can firmly pull the lacing wire into position, and no inconvenience is created by the wire dangling about, as would be the case without the aid of it or something similar. As the lacing progresses, the wire can be gradually unwound from the shuttle. Of course, it must be comparatively thin in construction to permit it to enter fine meshes.

I feel rather dubious as to whether I shall satisfactorily explain the operation of splicing. The term is associated with the unison of two opposite ends of a piece of work, thereby forming a compact cylindrical

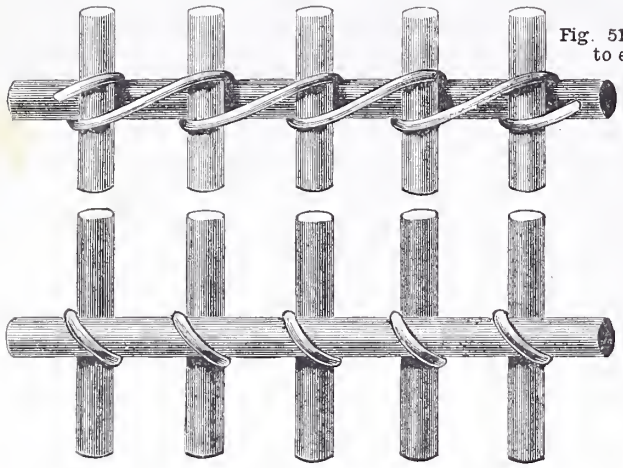

Fig. 51.—Wires laced to each other.

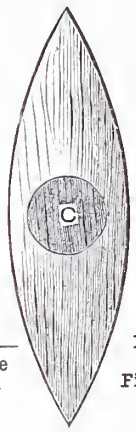

Fig. 56.—Shuttle (Plan).

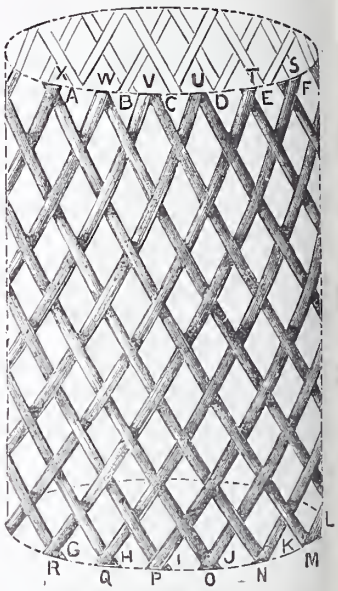

Fig. 60.—Work in Fig. 58 completely Spliced.

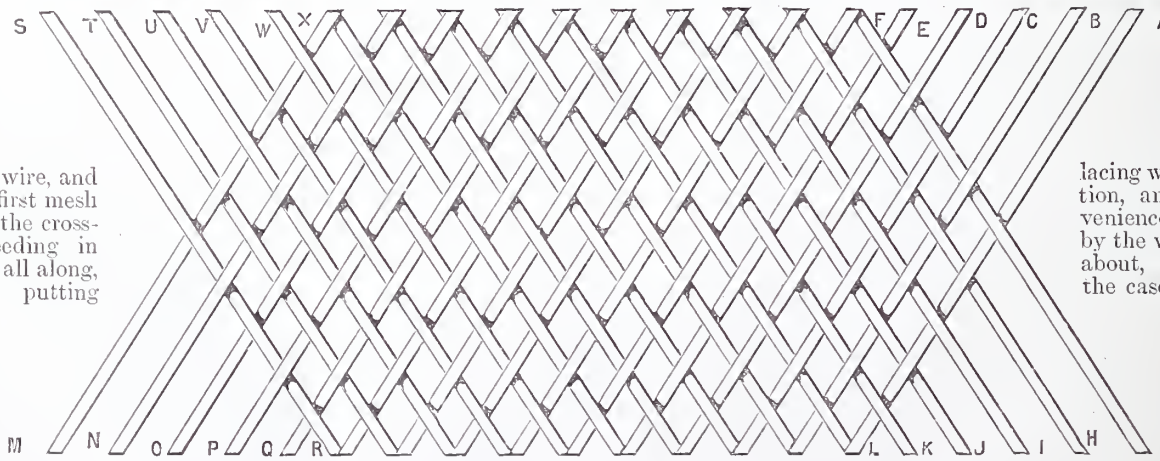
Fig. 58.—Piece of Work ready to be Spliced.



object. I must say that the performance, or the attempt at such, is very provocative of tantalisation, as I have personally experienced; for, although I am not a wire-worker, I have a desire to understand as thoroughly as possible what I am striving to convey to my readers, and, with this object, experiment, as well as circumstances will allow, after I have received practical suition from my practical friend.

In Fig. 58 is shown a piece of work supposed to be quite flat. To splice it, it would be bent as in Fig. 59, in order to bring both ends of it in contact with each other. In these diagrams I have lettered the wires that will be spliced. The two ends are brought closely together, when, if found to be too "springy," they could be held in position by having a wire twisted around them bodily. It would then be seen that the free portions of the wires A, B, C, D, E, F would be parallel with the free portions of G, H, I, J, K, L; and those of M, N, O, P, Q, R parallel with S, T, U, V, W, X—thus presenting a continuous and endless series of diamonds completely around the piece of work.

At this point the free portion of the wire A would be slipped under S, over T, under U, over V, and so on. Then the free portion of G, which will then occupy less length, should be slipped under B, over C, and so on. The free end, B, would be the next to be spliced, then T, by following which order the wires can be spliced to the same meshes as those first obtained by putting the wires together as in Fig. 53. The wires M, N, O, P, Q, R would be spliced in a similar but reverse manner to those of which I have just been speaking. Wire M would pass over G, under H, etc., as the other wires did in connection with their companions. When spliced, every mesh should be of the same size, and the wires should cross, each one over and under its fellows, in such a manner that it would be impossible for anyone to detect their junctions.

A piece of work so spliced would be capable of being bent to various forms without losing its strength. It will be found an impossible matter for anyone to pull apart a piece of spliced work without undoing the different wires; mere pulling affects nothing—*i.e.*, except to widen the work. Wire baskets, of which the bottoms are smaller than the tops; gas globes (one particular pattern), of which the middles are considerably wider in diameter than the tops and bottoms; and several other articles, are formed from spliced work which is at first of the same diameter at the top as at the bottom.

Of this I shall speak more fully when I arrive at the descriptions of the various articles alluded to; but to give an idea of the manner in which a piece of spliced work can be bent, I will say that the forms shown in Figs. 61, 62, and 63 are various shapes to which the work shown in Fig. 60 (drawn to much smaller scale, however, in the other diagrams) may be bent or pulled. Each piece would contain the same number of wires of precisely the same length and gauge as the others. No weakening takes place by thus forming the work to these shapes. Perhaps I ought to mention that when the wire is spliced as in Fig. 60 it has a tendency to bend inwards towards the middle, instead of being quite perpendicular all round, as it would be supposed from my diagrams.

For the purpose of cutting wire, the shears are utilised. If a number of wires of one length are required, such as for putting together, etc., they are not cut up one by one, but the wire is drawn from the coil for a distance as far as the shop will permit, and each of these lengths cut off from the remainder, until several are ready, when they, in a bundle as it were, are again divided together into the smaller necessary lengths.

On such occasions as these, it will be found best—indeed, I might say absolutely necessary—to fix the shears in a vice. One only of the handles of the former will be secured in this manner, leaving the remaining handle for the operator to use.

Of course, for cutting short work of only a few wires each time, the use of the hand shears will be quite sufficient.

## A NOVEL COMBINATION PENHOLDER.

BY W. R. R.

INTRODUCTION—PENHOLDER—CORK—INKING PAD—RULING WHEEL AND ATTACHMENT—DESIGNS FOR WHEEL—INK—DESIGNS.

*Introduction.—Multum in parvo* (much in little) is the demand of the utilitarians of the present age. A person requires a pocket-knife, and at the same time remembers he may some day also require a corkscrew, a glass-cutter, a file, a pair of tweezers, a saw, or even a magnet, which latter article is very useful for removing iron specks from the eye. So, for a little extra outlay, he purchases this miniature tool-chest in the form of a "Combination Pocket-knife."

Now, I propose to benefit the wielders of that instrument which "is mightier than the sword" by describing how to make a "Combination Penholder," hoping that it will prove acceptable and be a real boon, from the humblest student, struggling tediously to insert a neat mountain range in his examination map test, to the finished draughtsman engaged in "lining in" his mechanical drawings.

*Penholder.*—Having procured an ordinary wooden penholder and a piece (or pieces) of cork, proceed to shape the cork with a razor or keen-edged knife, as shown at *a*, Fig. 1. If a cork-borer (which is only a bit of tubing sharpened) is not come-at-able, the cork may be split in halves and hollowed out to fit the holder, and then fixed with glue. Some persons may object to this apparently clumsy innovation to the holder, but I can assure anyone who is troubled with writer's cramp that they have here a considerable relief, if not a perfect cure, for that disease of the nerves.

*Inking Pad.*—The next step is the construction of the inking pad for the ruling wheel, *b*, Fig. 1. This consists of a small piece of wood shaped as in Fig. 4, on which is glued a small cotton-wool cushion covered with silk. The pad is held in position by a ring of stout sheet brass and small spiral spring of wire, *c*, Fig. 1. The width of the pad ought not to exceed the diameter of the holder, or else some difficulty will be experienced in holding the pen in position against the edge of the ruler.

We now come to the most important part of the attachment—viz., the ruling wheel, *d*, Fig. 1.

*Ruling Wheel and Attachment.*—The shoulder for holding the wheel and attaching it to the penholder may be cut out of sheet brass or other suitable metal. Draw the pattern on the sheet brass with a needle-point or scriber same as Fig. 2. Cut out and shape on rod of iron same diameter as penholder. The shoulder will now resemble a pencil-point protector.

The ruling wheel itself now claims our attention. It may be made of wood or metal, and the desired pattern engraved upon it, but the most preferable wheel is one with a wooden body and indiarubber tyre, on which the design is cast. The indiarubber type-founding firms would doubtless cast a few strips of designs to order, from which suitable lengths could be cut and glued on to the wheel. Of course, for different designs a different wheel must be employed in the shoulder.

*Ink.*—Coloured ink suitable for using on the pad is made from aniline dye dissolved in spirits of wine, and can be made to dry with a glossy surface by the addition of a few drops of liquid gum arabic. Be careful,

**Fig. 1.—Pen complete. Fig. 2.—Shoulder for Wheel marked off on Brass. Fig. 3.—Shoulder and Wheel complete. Fig. 4.—Inking Pad. Fig. 5.—Designs for Ruling Wheel—*a*, *b*, Mountain Ranges for Map Drawing.**

however, not to wet the pad too much; a moist surface is all that is required.

*Designs.*—The designs shown in Fig. 5 are merely suggestive of the kind of work which can be turned off by aid of the *novel penholder*.

## FRENCH POLISHING: SPIRITING OFF.

BY DAVID DENNING.

NECESSITY FOR SPIRITING OFF—CLOSE CONNECTION OF BODYING IN AND SPIRITING OFF—SPIRITING OFF DEFINED—PRELIMINARY PROCESS—SPIRITING OFF PROPER—APPEARANCE OF GLOSS—FINAL TOUCHES—HINTS TO INQUIRERS IN "SHOP."

THE final operation in French polishing is known as "spiriting," or "spiriting off." By it the gloss, or shine, is put on the body previously applied, as directed in a former article. Rubber marks and smears of all kinds are removed, and the beautifully finished surface, which is known as a French polished one, should be the result. If bodying is important so far as durability is concerned, spiriting is more so with regard to finish, or fine bright gloss. However

well the rest of the work may be done, if the worker fails in spiriting, his previous efforts will, to a great extent, have been in vain. So far as mere polishing goes, and not alluding to staining, darkening, and other processes, with which a good polisher should be acquainted, the spiriting is perhaps the most severe test of skill. If a man can manage this part of his work really well, he may fairly be considered a competent polisher. To tell how to do spiriting off is a comparatively easy matter, but no amount of explanation will make anyone an adept at spiriting, for there is a knack in it which can only be acquired by painstaking practice. From this it may be gathered that the novice must not be disappointed if his early efforts meet with only partial success; or, to put it more strongly, it would be unreasonable for him to expect that, however closely he may follow ample and reliable directions, he will be able, without practice, to polish thoroughly. Perfection in polishing cannot be attained at once, so, while doing his best, it is no use for the beginner to fancy that he ought to be able right off to do what it takes years for professional polishers to learn.

I hardly know whether the first operation to be described in the present article should not rather have been included in the article on bodying in, for it partakes at least as much of that as of spiriting. It is not, however, of much consequence where it is placed, because at the beginning it is bodying and at the end spiriting. Perhaps I may be better understood by saying that the two processes, bodying and spiriting, merge into each other—there is no abrupt break, as between filling and bodying; hence the difficulty of precisely locating the work now under consideration in its proper chapter. One way out of the difficulty would have been to treat both in the same, and another to consider them all as included under a general heading of polishing. The two operations of bodying and spiriting are, however, so well defined—except for the intermediate stage—both in character and purpose, that to have done so would have been to mar the pages of Work, which is singularly free from technical errors. I may also say that what I have called the intermediate stage is not always practised, but the very fact of its being mentioned as part of the course of polishing shows that it is, at any rate, recommended when good work is wanted.

Perhaps a definition of what spiriting off is may help to make the operation clear. Briefly, it consists in washing the bodied surface with methylated spirit alone. This being understood, it is only necessary to say that the final bodying up, or first spiriting, whichever it may be called, consists in gradually reducing the quantity of polish in the rubber, and supplying its place with spirit. In other words, the polish is gradually reduced by the addition of spirit till all the polish has been worked out of the rubber. Thus the rubber may be moisteued, first with three parts polish and one part spirit instead of pure spirit; next time equal quantities; the third time three parts spirit and one part polish; while the fourth charging will be with spirit only. Of course, I do not mean to imply that these proportions must be, or in practice are, observed, but the explanation will illustrate the process more clearly than vague general description, so that I hope no one can misunderstand what is intended. At the last the rubber will be almost free from polish, and, as previously, it should be worked till it is dry, or as nearly so as possible.

When this stage has been reached the spiriting proper may begin, and a fresh rubber should be used for this purpose. It need not be a new one, but it should be one which has only been used for spiriting, and should have no polish on it. Instead of having only one covering of rag on its face, it will be better if it has three or four, which can be removed as they dry. If only one cover is used the spirit is apt to evaporate more quickly than there is any occasion for.

Now it will easily be understood that the spirit in the rubber partially dissolves the shellae or body on the wood, or at least that its tendency is to do so. That it does to a very limited extent is undoubted, unless the rubber is made too wet, when there is a danger of not only spiriting and smoothing the surface, but of actually washing away the body. This, of course, would be about as awkward a mishap as could occur, and it must be carefully guarded against. There should be enough spirit just to allow the surface of the body to be softened and smoothed, but no more, and it is almost unnecessary to say that the rubbing should be equal, and not more in one place than in another. As there is hardly any likelihood of the novice erring by using too little spirit, I may venture to say that the less of it the better in the rubber at a time. The rubbing should be gentle at first, becoming harder as the spirit dries off, and, of course, oil must not be used on the rubber face as when bodying. If there is any oil either on the rubber or on the work, the polish cannot be brought up.

If everything has been done correctly the gloss will soon begin to appear, and when it seems as good as it can be got, or is approaching that condition, the rubber ought only to be moved in the direction of the grain, and not across it or with circular motion. The final touches should be given with the soft rubber rag alone, the utmost care being taken not to scratch the surface, which is now softened by the action of the spirit. It will gradually harden, but for a time it should be handled with care, and nothing be allowed to come in contact with it, or it is very likely to be marked. It should also be protected from dust, for any settling on it may be retained by the polish, the lustre of which would certainly suffer.

Now, besides amateurs and novices, this article will no doubt be read by many cabinet-makers, of whom some, no doubt, will be masters, and perhaps dealers in furniture. Those who cannot keep an experienced polisher, or who, being in country places, may not be able to get the work done "out," will, I hope, derive some advantage from a perusal of these articles, to which I would now like to add a word of advice for their special benefit. It is that, circumstances permitting, any polished piece of furniture should be "wiped over" with a spirit rubber an hour or two before it is sent home, just to freshen it up; and if the surface is at all soft, neither packing mats, nor anything else likely to injure it, should be allowed to come in contact with it. The polishing on many things sent from London to the provinces is often not fit to be seen—from mat and other markings—till it has been "touched up" after arrival at its destination.

Notwithstanding all that has been said, it is quite likely that the useful, and almost overburdened, "Shop" columns may have further claims on them by someone asking how a particular kind of wood is to be polished; therefore, let me say that the directions for filling, bodying, and spiriting refer to all sorts; and that anyone finding himself in a difficulty must not merely say that he "can't manage" to polish, or that something is wrong in a general way, but must state as fully as he can exactly what he has done, and what is unsatisfactory in the result, if he wishes either me or any other member of the staff of Work to help him. Vague statements that the polish "did not look nice," or something of that kind, give no grounds to form an opinion on, and as no trouble is spared in answering replies, it is only fair that inquirers should help by making their statements as full and explicit as possible if they wish for advice. These remarks apply specially to the subject I have in hand, viz., polishing, but are more or less applicable to all.

In future papers, staining and other processes which are incidental to the polisher's craft will be fully discussed, and the next one will be on an easier method of finishing than by spiriting off—though, I warn readers, not so good a one—viz., the process known, among other names, as that of "glazing."

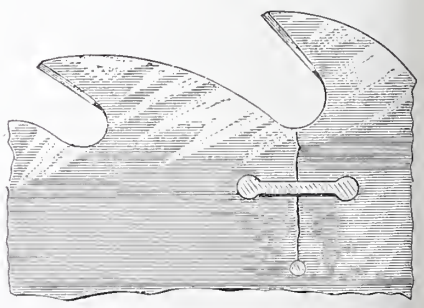
## HOW TO REPAIR A CRACKED CIRCULAR SAW.

BY M. POWIS BALE, M.INST.M.E., A.M.INST.C.E.,

*Author of "Saw Mills: their Arrangement and Management," etc.*

Cracks in circular saws may arise from a variety of causes, such as too hard a temper, striking a nail, saw bending in work, improper shape or size of the tooth for the wood being cut, etc.

Teeth with angular gullets are more liable to crack at the roots than those with rounded gullets, more especially if the gullets are not sufficiently large and deep to allow of a ready escape for the sawdust. If the crack is only a short one—say two or three inches in large saws—it may usually be stopped from extending by drilling a small hole at the extremity of the crack. To do this, a drill of the hardest possible temper will be required, and for this we have found Mushat's special steel suitable.



Mode of mending Crack in Circular Saw.

The drill must be run very slowly and be well lubricated. The hole should be slightly countersunk on either side. For saws up to 3 ft. diameter a hole of about ¼ in. diameter will generally be suitable; with saws above 3 ft. diameter about a ⅜ in. hole.

The illustration represents a portion of a saw showing a crack with a stop-hole drilled at its extremity, and with a yoke fitted across the crack. The stop-hole in this case is carefully plugged up. The yoke is made by drilling two holes, one at either end of the yoke, and by drilling and cutting away the

intermediate metal, as shown in the sketch. The opening should be countersunk, and a piece of steel plate carefully fitted and riveted into the place. The yoke must now be ground down until it is of exactly the same gauge as the rest of the saw and perfectly smooth, so that when the saw is set to work there should not be undue friction at this point. If the saw is a large one, and the fracture extensive, two yokes will probably be required.

## INTERNAL SANITARY FITTINGS OF HOUSES.

BY W. R.

### WATER-CLOSETS.

IMPROVED "BRAMAH VALVE" CLOSET—THE PAN CLOSET—WASH-DOWN CLOSETS—WASH-OUT CLOSETS — PEDESTAL WATER - CLOSETS — ARRANGEMENT OF SEAT.

*Various Forms of Water-Closets.*—One of the most important articles in a house, from a sanitary point of view, is the water-closet, and therefore I will give it precedence in this paper.

The water-closets usually fixed by plumbers during the last generation were the "Bramah Valve" and the "Pan" Closets. The former was invented by John Bramah about one hundred years ago, and has proved, when properly constructed and fixed, a most efficient machine.

*The Improved "Bramah Valve" Closet.*—Many improvements have been made upon the "Bramah Valve" closet, and Fig. 1 represents a pattern which may be relied on. The pan is a large one, and is connected to a small valve-box by means of a gun-metal flange; to this flange is attached a valve, about 3½ in. or 4 in. in diameter, which, when closed, presses tightly against an indiarubber ring sunk in the flange, thus forming a tight joint, and retaining a certain amount of water in the basin. Fig. 2 shows the action of the valve. When the handle is raised, it lifts a lever, which works the tumbler and throws back the valve; at the same time another lever connected to the stool-cock is raised, and, by opening the cock, allows the water to enter the pan. The closet is flushed by means of a 1¼ in. or 1 in. lead pipe (the size depends upon the head of water available), which enters the back of the pan, the water being distributed over the basin either by a copper fan or a flushing rim.

*The Flush.*—The flush may be supplied either by a cistern or by a constant head of water. In the former case the stool-cock and regulator, shown in Fig. 1, are not needed, the water being sent down into the closet by lifting a round valve in the cistern by an arrangement of cranks and wires working from the handle to the cistern; the after-flush or water to be retained in the pan being supplied by the water contained in the pipe after the valve in the cistern is closed. Flushing and syphon tanks are not suitable for this class of water-closet.

When a constant pressure of water is in the service-pipe, the stool-cock has to be used; and to obtain a proper after-flush, a regulator—such as may be seen at A, Fig. 1—is fixed so as to allow the lever attached to the stool-cock to regain its place slowly, the amount of time it takes to do so, and therefore the amount of water in the pan, being regulated by a small cock at the top. The regulator should be lubricated with glycerine. An overflow pipe is formed in the side of the pan, and is connected to the valve-box at the *back* of the valve by a 1½ in. lead **P** trap, as may be seen at Fig. 2. If the overflow enters in front of the valve, there is great danger of its becoming choked by the discharges from the pan. The flush should be so scattered over the pan as to send a certain amount of water through the overflow every time.

*Ventilation.*—Of very great importance is the ventilation of the valve-box for getting rid of the foul gas which is sure to collect between the water-seal of the trap and the valve, and also to prevent the syphoning out of the overflow trap.

A 1½ in. lead pipe should be carried from the valve-box at a sharp rise to the external air, and left open.

*Trap.*—The best trap to use under this closet is a 4 in. drawn lead **P** or **S** trap as may be required, taking care to thoroughly ventilate it.

*The Pan Closet.*—This wretched contrivance, shown at Figs. 3 and 4, has been most extensively fixed in the past, and is still being fixed by some benighted tradesmen, especially in rural districts. The only advantage which it can possess, to my knowledge, is a clean pan, and that is but outwardly, for anyone who has taken one apart after it has been in use some time, can testify to its disgusting uncleanliness.

The earthenware pan is set on an iron container of large dimensions, in which works a copper bowl or pan (from which the closet derives its name), moved by a lever in a similar manner to the valve-closet. Fig. 3 shows a section of the apparatus with the pan open. The service-pipe enters at the back, and is usually a ¾ in. lead pipe, which is, of course, much too small for the flushing it has to do. When the closet is used and the handle raised, the copper pan is thrown back, and the contents are precipitated into the iron container beneath, and thence into the trap, splashing all over the interior, and rendering it very foul in a short time. Very seldom do we find this container ventilated; and if it is, it is generally by means of a small hole in the top of it, open to the air of the apartment. Thus, at every flush the air which has been in contact with this foul interior of the container for some time is forced out into the room. To make matters worse, this defective appliance is usually accompanied by a lead **D** trap fixed under it. Under no circumstances should these closets be used.

*Wash-down Closets.*—Far cheaper and better than the Pan closets are the earthenware closets, which have become so generally used of late years. These closets are simple to fix, and, as they possess no working parts, are not liable to get out of order. Figs. 5 and 7 show two patterns of these closets, and Figs. 6 and 8 sections of the same, and most all others are modifications of these.

Fig. 5 is a wash-down, and may be considered as merely a trap with the mouth enlarged to form a pan. The back is made almost vertical, so that soil shall not be so liable to touch it, but fall straight into the trap.

This, however, does not always happen; and when it falls on the dry pan, it stays there, and defies the hardest flushing to thoroughly remove it. This is the one disadvantage of this pattern, but it may be overcome by flushing before using the appliance.

*The Flush.*—The service-pipe, which enters the back of the pan, should not be less than 1¼ in. in diameter, and should have at least 6 feet head of water, and be free from sharp bends.

A small stream of water is let into the pan by a little hole below the flushing rim, which falls on the paper in the pan, damps it, and sends it down to be carried off by the heavy flush. Flushing and syphon cisterns are very suitable for use with this pattern water-closet.

*Wash-out Closets.*—Fig. 7 is a wash-out pattern, and by its construction always holds a certain amount of water in the pan, as may be seen in the section, Fig. 8, thus preventing the pan from becoming foul.

*The Flush.*—The disadvantage of this pattern is that the two gallons of water which are allowed by the various water companies for each flush of a water-closet is not sufficient to thoroughly carry all soil, etc., through the trap, and thus a source of bad smells and probable stoppage may arise. With three gallons or more the case is different. The flush first strikes the water in the pan and throws it out, and the latter part of the flush rushes over the pan in a sheet, possessing great cleansing power and carrying all before it.

This only occurs if the service-pipe is not less than 1¼ in. in diameter and has a good fall, and is properly brought into the pan without any sharp bends. An after-flush chamber is sometimes made in the back of the pan, into which a certain amount of water is carried by the flush, and finds its way gradually into the pan through a small hole, after the flush has ceased. This is necessary when a flushing or syphon tank is used, as the water passes through the pan with great velocity until nearly the last drop, thus leaving the pan and possibly the trap partly empty. If, however, a cistern with a round valve and service-box be used, the water which is in the pipe after the valve is closed is quite sufficient to refill the pan. Regarding this same round valve and service-box arrangement, some plumbers make egregious mistakes. They imagine that the larger the service-box and the larger the air-pipe attached thereto, the greater will be the flush. This is true if the valve be one of Bell's, and the service-box is full of water, for then, when the valve is raised, the pressure of the water in the cistern is removed from the service-box, and it is necessary to allow the pressure of the atmosphere to bear on the water in the service-box through the air-pipe, which should then be the same bore as the service-pipe.

*Service-Box Ventilation.*—When a round valve is used, the only use of the service-box is to connect the valve to the service-pipe, and, in fact, may be regarded as part of the pipe itself; and so, when an air-pipe is connected with it and the valve is raised, the rush of water to the pan is retarded and impeded by the air drawn through the air-pipe by the water. The only use of an air-pipe with this arrangement is to allow the water, with which the service-pipe is filled after the valve is closed, to dribble slowly out into the pan. A small piece of copper or lead pipe closed over the top, and then pricked with a very fine bradawl, will be found quite sufficient. I have done many a satisfactory job by removing the service-box and round valve, and, after making the bottom of the cistern good, wiping a 1½ in. spindle-valve, such as is used for a pump, directly on to the service-pipe, after having previously tapped the side of the body to receive a piece of ¼ in. copper pipe, which has been brought to the top of the cistern and treated as before described.

*Pedestal Water - Closets.*—Earthenware

water-closets are often made with the pan and trap combined in one piece, thus forming a kind of pedestal which will stand alone. No elaborate construction of woodwork is needed for these closets, but merely a hinged seat, the pan being left bare all round, thus affording no chance for unseen accumulations of dust or dirt. Fig. 9 shows the best method of fixing this class of water-closet. The floor may be of tiles, or covered with lead, so that it may be well and frequently washed. The flush is obtained from a syphon cistern overhead, which should contain three gallons of water, and the pan is provided with an after-flush chamber. The disadvantages attached to this closet are: the impossibility of getting at the trap without taking the whole closet down, and thus exposing the house to the dangers of drain air; and in order to make the outside symmetrical to the eye, the trap is often badly formed internally, and presents odd angles and sharp turns to the passage of the soil.

*Points in the Selection of a Water-Closet.* — Great care should be exercised in the selection of a water-closet, the following points being closely looked to:—If possessed of working parts, see that no more than possible of such parts are liable to contact with the soil, and see that the tumbler arrangement is properly fitted; see that the flush is so arranged as to scour (not merely wet) every part; see that a large service of water is exposed to receive the soil; and if a trap be attached, see that the same is well formed and self-cleansing. The joint of the water-closet to the trap in the case of a valve-closet may be made by good red-lead stopping, or by an indiarubber ring. In the earthenware closets the pan should be set on the trap in red-lead stopping, and the trap should be joined to the soil-pipe either by a bandage joint or by flanges, in the case of a P trap; and by an indiarubber flange or ring when an S trap is used. Brass screws should be used to fasten the appliance to the floor. The connection of the service-pipe to the inlet-arm of the pan is best made with a stout indiarubber socket or connector, shown in section at Fig. 10.

*Lead Safe.*—A lead safe or tray must be fixed under every water-closet to prevent damage to the ceiling below, or a mess about the apartment, in case of an accident —such as the service-pipe or stool-cock leaking, or the pan overflowing. This safe should be the entire size of the space under the closet seat, and at least 3 in. in height, and should be drained by a $1\frac{1}{2}$ in. lead pipe, taken straight through the external wall, so as to show when anything is wrong. The end may be covered by a hinged copper flap, to prevent a draught blowing into the apartment.

*Arrangement of Seat.*—This requires attention. The riser should be hinged at one side, so as to open like a door. The seat also should be hinged, so that it can be thrown back; thus the whole space can be easily and frequently got at and cleansed. No covering, flap, or other cover should be allowed, for this often causes a nuisance by bottling up a bad smell for the benefit of the next comer. Some may object to this by saying it looks bad, but if the water-closet is not clean, it is the fault either of the apparatus or of the users. If the former, change; if the latter, let them change their habits and be clean.

*Position.* — As regards the position of water-closet apartments in a house, they should always be built on an external wall, or, better still, in a separate wing or off-set. The windows should be made to open properly, and, in addition, thorough means of ventilation should be provided; an opening of 24 square inches for every 1,000 cubic feet of air space being provided for inlet, and a corresponding opening for outlet, both connected with the external air.

Thus, every means should be taken to render these very necessary appliances harmless to health, leaving it to the users to keep them in that state, remembering that "Cleanliness is next to Godliness."

## ARTISTIC LITHOGRAPHY.

BY MISS ADA J. ABRAHAM.

### Chalk Work on Stone.

Practising with Chalk—Pad—Point of Chalk—Corrections on Stone—Scraping Tint—Lightening Tint with Needle—Solid Ink Work—Middle Tints—Working Tint into Stone—Transfer of Chalk Work—Splash Work.

For practising with the chalk, rule some squares on a grained stone, the same as before, and get accustomed to the working of the chalk by drawing various tints, such as Figs. 24, 25, 26. A small box should be used to put the chalk cuttings into, and bits of the chalk which break off should never be allowed to remain on the stone, or they would settle on it and not be easily removed.

It is better to use a pad instead of the board as a hand-rest for chalk work, and the student will find he can very often sharpen the chalk on the paper by twirling it round from right to left, and left to right, instead of continually cutting a point.

The finer the point is made, the finer the tinting will be, and the first tint drawn on the stone always tells in the work, and is therefore of much more importance than any subsequent ones. In drawing the outline on the stone the point of the chalk can be used, but for all flat tinting it is much better to work on the side.

Should a mistake be made in the tint it would not be well to scrape it, as it would destroy the surface of the stone, and show a different texture in printing to the rest of the tint. Fig. 27 shows where a portion of the tint has been made too dark, and scraped away without due caution.

If in making a tint any small portion of the chalk dots appear darker than the rest, they may be sometimes removed by placing the point of the chalk on that spot and suddenly lifting it up, when the chalk will adhere, and come off the stone. In this way a tint may be considerably lightened, but should never be worked on again, and unless this is carefully done, white specks will appear; and, also, after any part of the tint has been scraped, no future work would print if drawn in the same place, either on a polished or grained stone.

It is best to use the point of the needle to lighten tints, in the same way as it is used for stipple work; and it will be naturally understood that a tint can always be made darker, but very seldom lighter, satisfactorily. In fact, lithography is an art where

mistakes should never occur, for they invariably show more or less.

Any solid or ink work should be done after the chalk is finished, in order not to smear the drawing, and if in colour work the ink is put on first, care should be taken not to lift it off with the chalk, especially where the solid and chalk join. Figs. 28, 29 show good and bad methods of joining solid to chalk work. A ball (Fig. 30) is also excellent practice for shading.

A good rule to be observed in chalk drawings is that middle tints should be drawn as they are required to appear when finished, light tints a little darker, as chalk work loses its strength in printing — especially in light tints — unless worked well into the stone, which will make it appear a little darker than it really is; and dark tints should be worked a trifle lighter than required, as they sometimes clog up in printing, and so print darker, or even solid.

In chalk work the tint must be always worked well into the stone, and not merely put on the surface, else the grain will not hold the chalk sufficiently to print. Figs. 31, 32 give examples of the same tint, or rather the same tint as it appeared before it was etched, only in Fig. 31 it was worked firmly into the stone, and in Fig. 32 it was merely put on the surface. Chalk does not stand so well in printing as stipple work—that is, not so many good impressions can be obtained from it—as the artificial grain given to the stone wears away the work quicker than a polished stone would do; and also chalk not being so strong as the liquid ink, it is more affected by the acid. In the same way in making corrections on a grained stone after it has been etched, the utmost

Fig. 25.

Fig. 26.

care must be used, as if done in chalk it will not hold sufficiently to print, and therefore if a tint is required to be darkened it must be stippled with the pen, and that very judiciously for it to hold in printing. If the tint is required to be lightened it might be etched slightly with the acid; but it cannot be impressed too strongly upon the artist how carefully this must be done, else the tint will entirely disappear if too strongly etched, and may work up again if not etched sufficiently.

Chalk work is much more difficult to transfer than stipple, and is never done if a great number of good impressions are required. It is very good, however, for such work as bill posters, which could not be worked quickly enough in stipple, and also for artistic work, as it gives a softer effect; but for Christmas cards, almanacs, and work required to be transferred, stipple is the only satisfactory means of working.

Splash work (Fig. 33) is a very quick method of obtaining an even tint with very little trouble, and is very useful at times in giving a texture which cannot be obtained in any other way. It is done by having the stone flat, and gumming over that part where the tint is *not* required, or taking a sheet of paper having the outline of the tracing on it, then cutting out those parts where the tint *is* required, and laying it on the stone—it must be perfectly flat, and one or two lead buttons or pennies will keep it in position; it must not be lifted in any way or the ink will get underneath. Then fill a small tooth-brush with some ink, and, by holding another and rubbing the two brushes together, the ink will fall on the stone in dots. A small comb and brush—or a brush drawn across a penknife—would answer the same purpose. The closer the brush is held to the stone the nearer together the dots will fall, and the farther away the brush is held the larger the dots will become, and the coarser and more uneven the tint; also the more ink there is in the brush the coarser the dots will be.

If a dark tint is required, it should be done gradually, allowing the ink to dry before going over the same ground again, or the dots will all run together. It being impossible to lay the dots in any decided place in splash work, it should never be worked on faces or in any important parts of the picture; but it makes an excellent texture for such work as the foreground in a landscape or the background of a room, and can be done on either a grained or polished stone.

Much more could be written about the ways and means of working upon stone, but space does not permit. I trust that what has been already said will be a slight assistance to the student, and will, therefore, hasten to our next subject of practical work.

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* Work *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* Work *without charge, the notices given partake in no way of the nature of advertisements.*

### 46.—Lowth's Improved Patent "Unique" Honey Extractors.

The Improved Patent "Unique" Honey Extractors, invented and patented by Mr. T. Lowth, Riseholm, Lincoln, are such as appear to merit the attention of readers of Work who take an interest in bee-keeping. The "Section Extractor," shown in Fig. 1, is especially adapted for extracting honey from sections, and is fitted with cases for loose combs. It extracts the honey from three sections, and the can, which is 10 in. in diameter, will hold 10 lbs. of honey. A perfectly steady and easy revolution is produced by

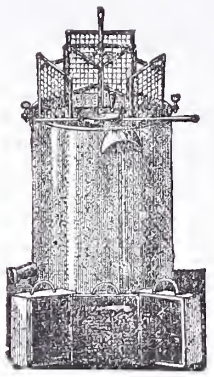

Fig. 1.—Lowth's Section Honey Extractor.

the detachable cages, which cause the ejection of the honey from delicate combs, such as are usually found in sections, with the least possible labour and waste. The inventor claims that the machine will be most useful and handy, especially when a good harvest of section honey is secured, for extracting the contents of unevenly built-out, and therefore unsaleable, sections, thereby preserving the combs and producing the finest samples of extracted honey in saleable form or for exhibition purposes, the quality and brilliancy of the honey being preserved. Thus, by using this extractor, the honey is saved from becoming candied by being left in the sections, and clean built-out combs are provided, which are valuable for securing the early spring crop. Frames or sections, containing honey to be extracted, should be carefully uncapped, placed in cages, and a few revolutions given to eject the honey; the combs can at once be returned for bees to refill, or preserved for future use. Loose combs should be placed in cases provided, and the honey extracted in the same way. The price of this machine is 7s. 6d., and can be sent post free for 9d., in addition to the cost.

The "Bar-Frame Extractor," shown in Fig. 2, is made entirely in metal, with movable folding

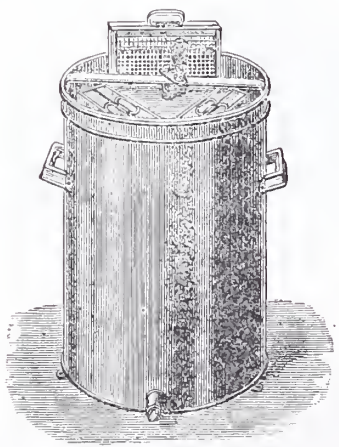

Fig. 2.—Lowth's Bar-Frame Honey Extractor.

cages, and combines in itself all the latest improvements in extractors. By its aid honey is extracted at one operation from three standard or shallow frames, 1 lb. or 2 lb. sections, and loose combs from skeps. The combs are held firmly in position during the process of extraction, thus preventing any breakage of the comb or mess. Each cage can be easily removed for inspection of combs, uncapping, or putting in fresh combs when desired. Brood combs, subjected to the action of the machine, are not splashed or chilled. The internal arrangement of the extractor forms a light running machine, imparting considerable centrifugal force to the revolving cages. The necessary speed for ejecting the honey can be at once obtained, thus saving much time and labour expended in the operation when carried out by other means. The price of this extractor is 21s., or 22s. 6d. if packed in case. Any size machine can be made to order.

The machines above noticed may be described as being thoroughly well made, portable, easy-working, and simple in construction. The internal parts can be promptly removed for cleaning, if desired. The special feature in the Bar-Frame Extractor is its capability for all-round work—namely, the extraction of honey from frame sections and loose combs. The internal arrangement of the cages is such that the honey is more easily ejected from the combs at a lower rate of speed, entirely dispensing with cog-gearing, which is absolutely unnecessary in this extractor. The movable folding cages, moreover, do away with all risk of the comb being broken either in or out of the machine. The covering-in of the revolving parts at the top prevents splashing and chilling of brood combs while the machine is in motion, so that there is no need for a top cover. The height of the cylinder, which forms the case, is 2 ft. 2 in., and it is 17 in. in diameter. About 35 lbs. of extracted honey can be held under the cages. The cylinder forms a useful vat or receptacle for honey when not in work.

### 47.—"Woodwork."

This is the brief title of a handy little volume, designed to meet the requirements of the Minute of the Science and Art Department on Manual Instruction. It is written by Mr. George St. John, Handsworth, Birmingham. It is published by Messrs. William Blackwood & Sons, London and Edinburgh, and its price is 1s. It is intended to point the way to the establishment of classes in manual instruction in elementary schools, and to show the cost of the necessary outfit in tools and benches, always supposing that the school in which such a class may be established is possessed of the necessary accommodation for a workshop. The cost, as to plant, etc., may thus be easily reckoned up; but what if the elementary school is without any adjunct that can be utilised as a workshop, and the School Board, or school managers, as the case may be, have to provide the wherewithal for the payment of an efficient instructor in the person of a skilled artisan, for it will be utterly useless to place the boys at the mercy of an unskilled amateur? "My Lords"—I am referring to the Minute—touch but lightly on the teaching part of the business. "The instruction *may* be given by one of the regular teachers of the school, *if he is sufficiently qualified;* if not, he must be assisted by a skilled artisan." No very great effort of brain power was required to evolve this permissive remark. There are a few teachers who could do the work, as I know, but in the great majority of cases the services of the skilled artisan will be a *sine quâ non*. Again—"The work of the class will be examined by the local inspector of the Department, accompanied, *if necessary*, by an artisan expert on the occasion of his visit to examine in drawing." Which shows that "my lords" are a little bit doubtful about the competence of the local inspectors. The matter given in the book itself is excellent, thoroughly practical, and sufficient for all elementary purposes; but the bench vice, shown in the engraving of the carpenters' bench in page 31, is an ancient form, and by no means convenient to work. There are as cheap and better forms in existence. It is to be hoped that the present volume will meet the purpose for which it was designed, and find favour, in the bargain, with the large body of amateur wood-workers. Its value in schools, however, would seem to turn more upon some better support than is already given to the subject of elementary technical education by the Education Department.

The Editor.

# SHOP:

## A Corner for Those who Want to Talk It

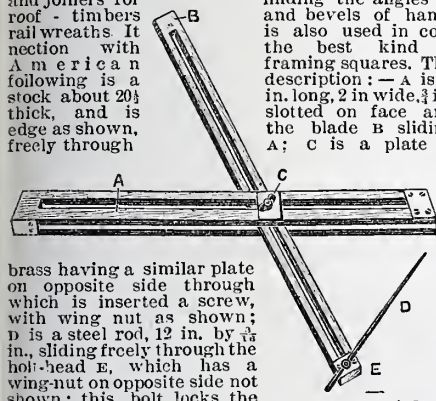
*** *In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—Letters from Correspondents.

**Rate of Circular Saw.** — A. R. (*Scorrier*) writes:—"In my letter (see WORK, No. 116, page 187), wrongly ascribed to A WOODWORKER, it is *Woodworker, and not myself*, who thinks *that the speed of a circular saw and feed of timber may be reduced in proportion to the power, and be an advantage.* I omitted to put this conclusion of WOODWORKER'S into italics in my letter on page 187."

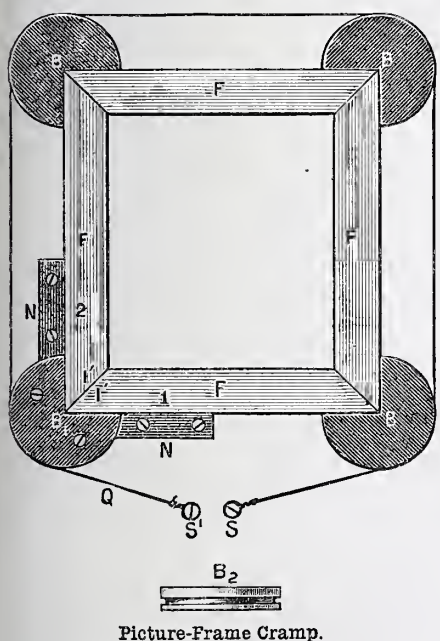
**Instrument for Bevels, etc.**—J. S (*Londonderry*) writes:—"The following is a sketch of an instrument used in the United States by carpenters and joiners for finding the angles of roof-timbers and bevels of hand-rail wreaths. It is also used in connection with the best kind of framing squares. The following is a description:—A is a stock about 20½ in. long, 2 in wide, ¾ in thick, and is slotted on face and edge as shown, the blade B sliding freely through



Instrument for Bevels.

brass having a similar plate on opposite side through which is inserted a screw, with wing nut as shown; D is a steel rod, 12 in. by $\frac{3}{16}$ in., sliding freely through the bolt-head E, which has a wing-nut on opposite side not shown; this bolt locks the steel rod in any position, and by unscrewing the wing-nut the rod can be projected out to the full length (12 in.), and can make a complete revolution round E. I shall feel obliged if some correspondent of WORK (and I know there are some in the United States) would describe how this is used."

**Picture-Frame Cramp.** — S. C. T. (*Knutton*) writes:—"I am sorry to have given you the trouble of returning my first letter for lack of clearness, but



$B_2$

Picture-Frame Cramp.

will endeavour to do better this time. The contrivance is for gluing up picture frames. First take the two pieces 1 and 2 (as shown in diagram), glue the joints 1', 1', and put them in the corner, fastened down to the floor (marked B N), and squeeze them together. Treat the other joints in the same way, placing the three pieces marked B on the joints as shown. Then fasten a piece of strong cord (marked Q) at S, and pass it round the circles, pulling as tight as possible, and tie at S, not letting the string go looser. The pieces should be constructed as follows:—B, B, B, B are circles of wood, about 4 in in diameter (size is immaterial), 1 in. thick, with a groove turned (as shown) near the bottom edge (as shown at $B_2$); each circle has a quarter of a circle cut out of it after turning. One of the blocks, marked B', is fastened to the floor, or a level table, by screws, and N, N are two slots of wood same thickness as circles, and about 4 in long, fastened also to the floor; S', S are two screws let into the floor to fasten the two ends of eord (Q) to. The picture frame should be left in the 'stocks' all night, and then next morning take it out, and it will be found quite firm; then saw a slit with a fine saw through the angle of each corner, and, having glued a piece of match-box, put it in the slit; when hard, trim off, and it will be found quite strong enough for small frames. For large frames, of course, ordinary methods are adopted."

**Repairing Set-Pan or Copper.**—T. W. P. (*No Address*) writes:—"Sometimes a cast-iron set-pan or copper will burn through in one small place, perhaps, which may be a flaw in the casting, or a place subject to more heat than other parts of the pan. A temporary method of stopping this may be of use to some fellow-readers, who perhaps do not want the trouble and expense of a new pan. Take a brass shank button, and carefully rimer the hole in pan till the shank will just pass through. Cover the back of button thickly with white-lead; press the shank through the hole, and wedge on the outside of pan with a small taper nail, which will draw the button quite close to the pan, making a good sound job, which will last for months, and perhaps for years."

### II.—Questions Answered by Editor and Staff.

**Papier-Mâché Rollers.** — F. P. (*Swansea*) should have named the purpose for which the rollers are required. Without a fair statement of the question, it is scarcely possible to give a satisfactory answer. Are they for rolling photos? If so, the sellers of photo. apparatus would supply them. As makers of articles in papier-mâché pulp generally, Messrs. McCallum & Hodgson, Summer Row, Birmingham, might be applied to; or with the directions already given in WORK, why could not F. P. make the rollers himself?—S. W.

**Stationery**—RULER.—Your best plan will be to obtain an index from the publishers or through your bookseller, and look it up, and order your deficient numbers from it. But the best plan of all would be to order *all* numbers which you have not got, and so make your volume complete. There may be many things contained in them which would be of interest to you. There are books published upon bookbinding which are very high-priced, and which contain much information of a certain kind, but not what you desire. There is, however, a series of articles appearing in the *British Bookmaker* upon stationery binding which will suit you, and which you should not fail to consider. The magazine is published monthly, and the price is 6d.—G. C.

**Cabinet-Makers' Tool-Chest, and Clockwork Cradle Swings.**—IMPATIENT (*Thirsk*) —I myself, and others also I believe, have given several useful suggestions relative to tool-chests in "Shop." A paper, however, on this subject will require a portion of the body of the magazine. Concerning the most suitable handles, I think that you, as a cabinet-maker, ought to be the best judge. Unfortunately I do not know where you can obtain the clockwork cradle swings; but perhaps this note will elicit information from someone possessed of such. As you saw one in the York exhibition, perhaps some of our readers resident in that county will step forward for our mutual benefit.—J. S.

**Portable Stand for Optical Lantern.**—F. C. (*Londonderry*) asks for a sketch of a portable stand suitable for a biunial lantern. A modification of the ordinary photographer's tripod, as shown in Fig. 1, forms an extremely portable stand for the purpose, which can be readily made by an amateur carpenter. The upper limb of each leg is formed of a couple of strips of ash or mahogany, 30 in. by ¾ in. by 1 in., the lower limb being a similar 30 in. strip of wood, which measures ¾ in. by 1 in. for 27 in. of its length, and then widens out in the form of a wedge from 1 in to 1¾ in. A mortise is cut through the wood just where it begins to widen, and a flat plate of brass, 2½ in. by ½ in. by $\frac{1}{16}$ in., is drilled and filed to the form of Fig. 2, and inserted and screwed into the mortise in order to form the hinge, as shown in Fig. 3, the ends of the two upper wooden limbs being slit with a saw, and then hinged one on either side of the lower limb, as indicated in the cut. A 2 in. length of ¼ in. iron or brass rod is now tightly fitted into a hole bored through the widest portion of the wedge, with an equal amount of the rod projecting on the outside in either direction. These ends of the rod are made to fit into holes bored in a suitable position partially through either of the movable limbs, by which means the upper limbs will be rendered rigid upon the stand being opened. The lower end of the central limb will require to be pointed and provided with an iron toe-cap (Fig. 4), (to be obtained from Mr. Platt, Birkbeck Works, Birkbeck Road, Kingsland, N. No. 87 in list; 1½d. each); and the outside of each of the upper limbs must be furnished with a small brass plate (Fig. 5), which may be fixed in position by means of a couple of brass screws, as shown in Fig. 6. These plates are No 7 in Mr. Platt's list; 2d. each. The table top of the stand must, of course, be made of a suitable size, according to requirements, but a board 12 in. by 18 in. may be taken as an example of a useful size. The bottom board of this diameter (shown in Fig. 10) should be furnished with a couple of cross ends, and a raised framework screwed round the upper surface, as shown in Fig. 1. The two long sides of this framework are 18 in. long and 6 in. wide in the centre, tapering off to 2 in. at either end (see Fig 7). The two strips for the ends of the framework will be 2 in. wide, and the length of the width of the board. The framework is put together with halved joints, as shown in plan in Fig. 7, and afterwards securely attached to the base-board. The movable table top, which may with advantage be a few inches larger than the base, is hinged to the apex of the raised framework by means of a couple of ordinary brass glass-plates, one of which is to be bent to right angles in the position shown by the dotted line in Fig. 8, and then screwed to the underneath of the table top, and afterwards pivoted to the framework at A, Fig. 7. The slotted arms, by which the position and angle of the table top is adjusted, consist of a couple of stout pieces of brass plate, 6 in. in length, drilled and filed up to the form of Fig. 9. These are pivoted by means of a screw to the edge of the board, and then secured at any desired position by means of a milled screw working in a plate affixed to the side of the framework in the position shown at B, Fig. 7. Mr. Platt's T-screw and nut-plate, No. 105, at 6d.

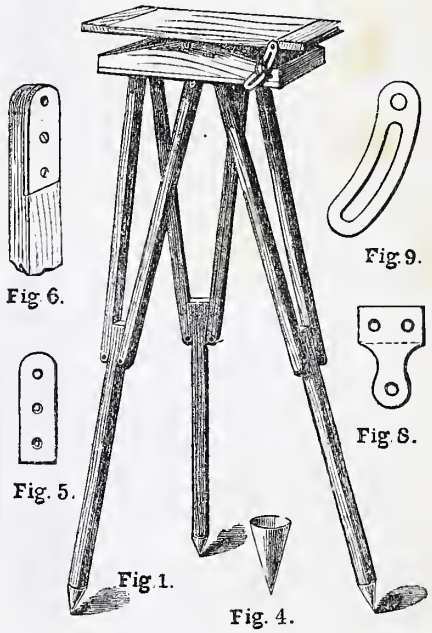


Fig. 6. Fig. 9. Fig. 8. Fig. 5. Fig. 1. Fig. 4.

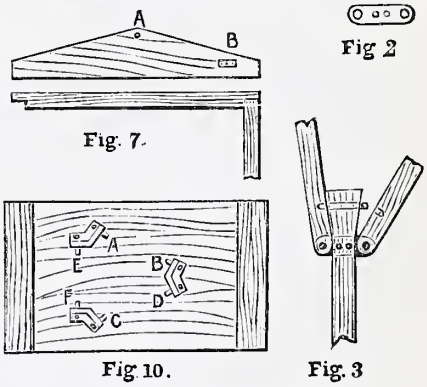

Fig. 2

Fig. 7.

Fig. 10.

Fig. 3

Stand for Lantern.

each, will answer the purpose. The stand is finally completed by the addition of a set of thin bearings, which are affixed to the under-side of the base, in the position indicated in Fig. 10—the distance between A, B, C, D, and E, F, being about 6 in., which will then enable the upper limbs to be sprung on to the projecting pins of each bearing. Mr. Platt can supply a set of thin bearings at 2s. 6d., No. 79. The stand is, of course, stained and varnished, or polished, according to taste. Although a tripod stand of the above description is frequently employed for lantern purposes, it is not by any means the best form of support to my mind, as the spread-out legs have a knack of getting in the way in the dark, which is very exasperating to the operator, and frequently damaging to the apparatus.

Another plan, which is far preferable to the stand above described, is the method adopted by Mr. T. C. Hepworth, a well-known lanternist of considerable experience. The four lower corners of the containing case of the lantern are furnished with iron sockets, into which four substantial iron legs (1 in. wide and $\frac{1}{16}$ in. thick) can be readily slipped, the lower end of each support being turned in the form of a toe, which is provided with a hole in order that the legs can be affixed to the floor by means of screws. In Nos. 37, 38, 39, and 41 of the *Camera Magazine* I have described and illustrated several other forms of photographic camera stands, some of which are capable of being utilised for lantern work.—C. A. P.

**Linesman's Galvanometer.**—J. N. (*York*).—I will endeavour to comply with your request by sending in to the Editor an illustrated description of a linesman's galvanometer. It would occupy too much space in "Shop," as there will be several illustrations.—G. E. B.

**Watch Work.**—APPRENTICE.—I hardly like to advise; but if you have a fancy for watch making—or rather watch jobbing, I suppose you mean—why, there is many a worse-paying trade, also many better. If you go as an apprentice, make sure that the man is a practical one or keeps good workmen, and gets good work. It would not pay you to waste seven years at a shop where they clean watches at a shilling each. A *good* watch jobber can always get a place, and keep it if he likes, and at the same time earn good wages if at all up to the mark. Of course, wages vary in different towns, but roughly from 35s. to 50s. per week. There are plenty of jobbers about that are not worth their salt; perhaps I ought to say butchers, not jobbers or repairers. We are open to take a good jobber, and the last we paid on an average £2 a week and over, sometimes over £3, seldom under 35s.: but you must make yourself efficient, then you need not want a job long. Any further particulars if desired.—A. B. C.

**Oiled Paper.**—MAC.—(1) I assume from Mac's inquiry that he desires to prepare some of the above; I therefore give him the required information, which will enable him to do so with very little trouble, and make a good job of it. First, let him get four ordinary plasterer's or builder's laths, each of them to be longer than the largest sheet of paper he proposes to operate on, and tack, tie, or pin them together at the corners so as to form a frame just the size of the sheet he intends to use, and then to this frame evenly pin or otherwise attach the paper by its edges. Having done this so that the paper will not slip, let him get some good *boiled* linseed oil—not the *raw* oil—and a brush, and then, placing the frame and paper on a flat board or surface, go lightly and evenly all over it with the brush dipped in the oil, until it is evenly covered; and when this is done, set it on one side to dry, taking care, if he stands it in a vertical or sloping position, to reverse it two or three times during the first hour or two, in order to prevent the oil draining to the lowest part and making it "streaky." When dry—say, in twenty-four hours—if not transparent enough, let him give another coat to the reverso side of the paper, taking care in both cases not to use too much oil at once; and when dry, he will find it just what he wants. I have made hundreds of sheets of this for cultivating boxes and frames for raising seeds, etc., as it acted a deal better than glass, at the same time that it gave shade and prevented scorching. (2) No licence would be required under the conditions stated.—C. E.

**Lathe Wheel.**—W. B. R. (*Westbury*).—I certainly do prefer the V grooves and gut-band, but the flat strap is about as good, and with a flat strap it is not necessary to have the rim of the wheel turned, so that saves expense. You could have a 24 in. or 30 in. wheel of about 70 lbs. with two steps for the belt—say, for the largest 24 in., and for the second speed 22 in.; let these work to two speeds on the mandrel of 3 in. and 5 in., and that will give you speed ratios of 8 and 4½ to 1, which is all you want for turning wood. I should try for such a wheel near at hand to save carriage; try at the nearest large ironmonger's or foundry. You must have it bored, but it need not have the rim turned.—F. A. M.

**Cleaning Carpet and Mattress Tick.**—W. B. (*Mildmay Road*).—If there are any special patches of grease on the carpet, pound and mix together fuller's-earth and magnesia in equal quantities; make into a paste with boiling water; lay this on the places, leave it till dry, and when it is thus brushed and beaten off, it will bring the grease with it. If the carpet is only generally dirty and faded-looking, after a thorough beating put a pint of bullock's gall into four gallons of soft water soapsuds, and with this scrub the carpet with a brush having long and softish bristles. The gall will brighten up the faded colours. As to the tick of spring mattress, W. B. is strongly advised to remove and have it washed—it cannot be thoroughly purified without; but if this is impossible, something may be done in the way of removing stains, grease, dirt, etc., by sponging with benzine.—S. W.

**Needle Telegraph Instruments.**—H. H. (*Aston*).—This is rather a large order for "Shop" column, as to give detailed instructions for making these instruments would require much more space than can be spared here. I have, however, drawn out such an instrument, and Fig. 1 gives the general appearance. The case should be of wood, with a glass front and brass handle. What is really wanted is a double bobbin, wound with about 400 ft. of No. 36 silk-covered wire; the two coils should be joined together, as will be seen at the top of Fig. 2. A strongly-magnetised needle is mounted on an axis to swing freely between the coils, and a light pointer is fixed to the axis so as to come to the front of the dial. The signs are made by making the current from a battery flow in different directions through the coil, by which the needle and pointer is deflected either right or left, according to the will of the operator. This is effected by what is called a commutator. Its construction will be seen from Fig. 2. It consists of a cylinder of boxwood, with a brass handle which projects in front of the case (Fig. 1). On its circumference, parallel to its axis, are seven brass strips, which are connected at the end by insulated wires in the following manner: A with B and C, F with D, E with G. Four springs press against the cylinder, X and Y are connected with the poles of the battery, M with the earth-plate, and N with one end of the coil. The line to be used between two stations may be No. 28 B.W.G. well insulated. I think that H. H. can easily make his instruments from this description, as I could not go into more detail at present.—W. D.

Fig. 4

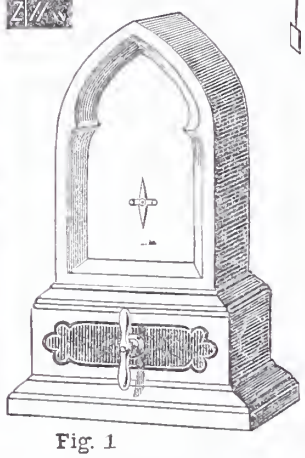

Fig. 1

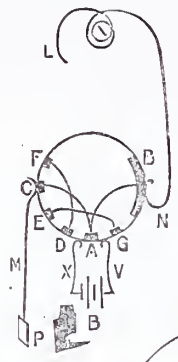

Fig. 3

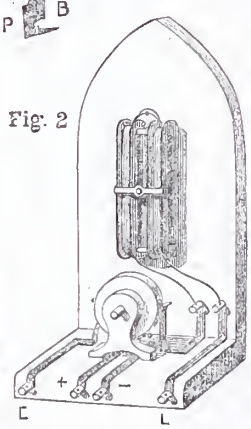

Fig. 2

Needle Telegraph Instruments.

**Carving Designs for Bedstead.**—H. J. (*Bradford*).—I should think that you might find some suggestions in back numbers (see Indexes to Vols. I. and II.). Two good publications sometimes containing Italian carving are *The Cabinet Maker* (6d. monthly) and *Furniture and Decoration* (6d.). You see, one cannot do justice to carving designs in a small space; hence the reason I disappoint you for the present.—J. S.

**Strength of Metals—Patterns, etc.**—BRAMAH.—A very useful book, giving weights and strength of metals of all kinds, is Spon's "Engineers' Tables," price 1s. With regard to patterns of tinware, there were several articles on the subject in WORK, Vol. I. Have you seen them?—R. A.

**Dead Black.**—BRASSWORK.—For a good hard dead black, try "Enamelloid" (see "Guide to Good Things," WORK, No. 106). I have used this for blacking camera, lens, and so on, and find it answer admirably.—R. A.

**Piano Stool.**—F. D. B. (*Stamford Hill, N.*).—I believe that Mr. Gleeson-White, in an article on an Overmantel, and in another one dealing with a Sideboard in turned work, gave the name and address of a firm who supplies amateurs. Refer to the Indexes for the articles alluded to.—J. S.

**Elliptic Curves.**—J. B. (*Reading*).—The matter has been treated fully in former letters, my statements being based on standard works on geometry, to one of which I referred, as being, to my mind, the easiest to understand. As to *foci* not being the plural of *focus*, I must refer you to a dictionary.—F. C.

**Bore Hole.**—W. R. (*Burnbank*).—There is no better tool than the D bit. We are always boring holes of this character, sometimes as much as 8 ft. or 9 ft. long by from 2 in. to 2½ in. diameter. You will necessarily have more trouble with an inch hole than with one larger, because of the choking caused by the borings, and must also put up with the slowness of the process. In large drills we form a lip on the cutting edge to break up the chips, but this is not practicable with small ones. You must withdraw the drill to clear the hole as often as it becomes choked.—J.

**Views on Glass.**—A. E. S. (*Glasgow*).—I am not familiar with the method you name of obtaining views on glass, if it is done by means of a transfer from copper-plate; but there is a process of decorating glass which is something similar to your method, and from which perhaps you may gain a few hints. Designs are traced, in this case upon ground glass, with copal varnish, the best being used, as clear and devoid of colour as possible. It is allowed to stand in a warm, dry place for eight or ten hours until thoroughly dry, then immersed in clear cold water for five or ten minutes, and allowed to drain, being afterwards exposed to a moderate heat; and if the varnish is good it will be firmly set. The very best colours are afterwards used for colouring. Now, if your black was not a good one, it would account for it turning a smoke colour; and it strikes me that perhaps you did not give the varnish time enough to thoroughly dry before subjecting it to heat.—W. E. D., JR.

**Kodak Detective Camera.**—NOVICE.—There are many hand cameras in the market of about equal merit; it would be somewhat invidious to select one as superior to the rest. The qualities necessary for really practical work are, in the first place, simplicity; and secondly, effectiveness and non-liability to get out of order. The "Faeile" and the "Ideal" are excellent, good work being easily done with either. In mentioning these we do not insinuate they are better than many others. In selecting, much depends on the fancy of the purchaser. With regard to the "Kodak," it is especially constructed to work with the roller slide and films. It is very simple; and where weight is of consequence, of course much less weight than if those cameras are used that require glass plates.—D.

**Camera Bellows.**—A. W. (*Paisley*).—Your design leaves nothing to be desired with regard to rigidity, but many other plans have the advantage of working almost automatically, thus saving time. According to plan sent, more time would be occupied in setting up and taking down the camera, as no provision is made for folding. The usual make of stretchers, besides acting as struts, permits the back of the camera to be swung, and by merely loosening or tightening a screw, no further trouble is required in opening and closing the apparatus than this; and the rapidity with which this can be effected is considered very important. The bellows seem to be one of the earliest patterns made.—D.

**Mounting Prints on Linen.**—H. N. (*Ipswich*).—Tack the linen or calico as tightly as possible on a frame or board, then coat it (the linen) with strong size, and leave till nearly dry. The back of the print must then be well covered with paste—this will be better done twice, the second time after leaving the first coat to soak about ten minutes—then place the print on the strained linen, and dab it all over with a clean cloth. When thoroughly dry, give face of print a coat of thin size. When dry again, repeat this. The size should not be too thick, or it will blister; nor too thin, or it will sink in; but a little practice on some inexpensive thing will soon teach you more than I can. When the two coats of size are thoroughly dry, varnish with white crystal varnish, such as paperhangers use, and which you can obtain at any good oil shop. When the varnish is quite set and dry, cut the thing off the frame, and it is ready for framing or mounting. A very good plan of my own for, say, a children's nursery is to simply wet the back of coloured print with a clean sponge, then paste (two coats, as above) round about ¾ in. of margin; stick it on the wall; it will strain quite tight. When dry, size and varnish as above. This gives a very cheerful effect to the room.—F. B.

**Chemist.**—A SUBSCRIBER FROM NO. 1 (*Southampton*).—Write to the Secretary of the Pharmaceutical Society, Bloomsbury Square, London, W., and ask him to send you a prospectus of the next preliminary examination. This will probably contain all you wish to know; if not, send in another query to WORK. Your son should have passed this examination before being apprenticed, so that he could now confine his studies to chemistry. Your best plan is to push him through the preliminary as fast as possible.—F. B. C.

**Decorative Window Frames in Cast Iron.**—S. R. (*Manchester*).—The illustrations in No. 95 (Vol. II., page 689) were original designs, and have not, to the best of the designer's knowledge, been carried out by any manufacturer for "stock." It will be necessary to have patterns made, and place them in the hands of an iron-founder.—H. P.

**Drawings for Patent Specification.**—A REGULAR SUBSCRIBER.—The Patent Office is peremptory in its regulations as to drawings, and we should by no means advise sending a lithograph in lieu of the prescribed Indian-ink drawing on white paper.—C. C. C.

**Crank Pin.**—FAITHFUL READER (*Aberdare*).—The thickness of metal in brasses should be about one-ninth of the diameter of crank pin; the width of strap one and a half diameters. The connecting-rod end should extend one diameter beyond the crank pin, and have a breadth of two diameters of crank pin. The length of the crank pin should be one and a half diameters. These are rough proportions; for good work the stress on each part should be calculated, and the dimensions determined in accordance with the results.—F. C.

**Staircasing and Handrailing.**—J. W. F. (*Cheshire*).—Arrangements have been made for papers on these subjects. Staircasing will be treated separately.

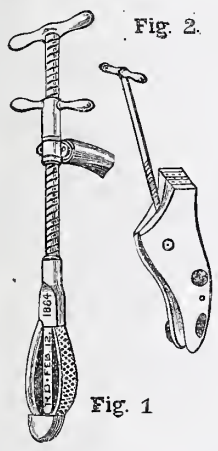
**Spoon Boxes.**—A FRET-WORKER.—Have you searched the catalogues of the firms who deal in fret-work, who advertise frequently in WORK, for fret-work designs of the above? If not, do so. These are the only mediums I am acquainted with through which you are likely to obtain such; unless you inquire also of the editor of the *Amateur*, Messrs. Zilles & Co., Finsbury, London, E.C.—J. S.

**Examination Papers.**—ASPIRANT.—If you wish to obtain copies of the examination papers on electrical engineering given at the Technical College, Finsbury, I should advise you to apply to the secretary for them. I should do so if I wished for them, and should enclose a stamped addressed envelope for reply. You will then learn whether or not they are obtainable.—G. E. B.

**Paddle-Wheel Electro-Motor.**—G. P. (*Bebington*).—The paddle-wheel electro-motor you saw was probably one for rotating vacuum tubes. One for this purpose will be described at the end of the series of papers on Induction Coils. Had you told me what you wanted the motor for, I could have given you instructions for winding it; but I cannot undertake to describe half a dozen different motors on the chance of one of these suiting you. In any case, you must either have a lathe in which to turn the parts of a motor up true, or get them turned for you by someone who has a lathe, whether it is a paddle-wheel motor or any other type.—G. E. B.

**Fret Machine.**—R. W. (*Radnor*).—Enough upon the subject of utilising sewing machine parts for fret machine construction has already appeared in WORK. Consult the Indexes to Vols. I. and II.

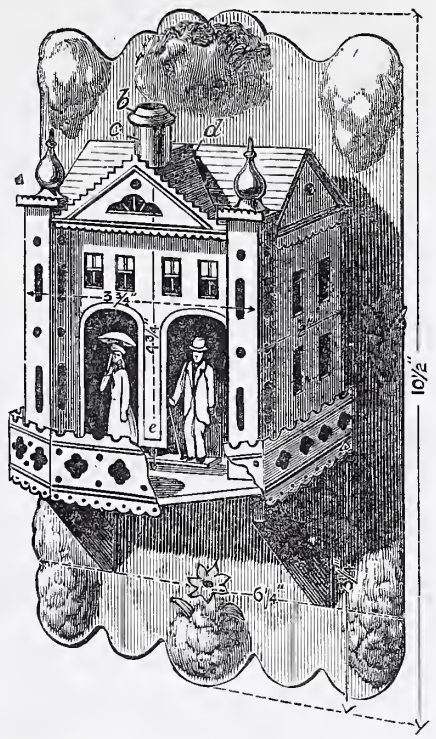
**Screw Lasts.**—D. (*Sunderland*).—As you ask for an "American screw last," I give in Fig. 1 the "Boss," price 12s. 6d., obtainable at the Wells Wire Quilting Company, Leicester. This is a length, as well as a girth, stretcher. Fig. 2 is a joint stretcher only, and can be bought at any leather-seller's shop; cost from 3s. 6d. Should you mean the last for repairing upon, there is only one with a screw in the market, which is called the "Perfect" repairing machine, price 3s. 3d. But if, as you say, you have one, you ought not to need another, as it, with its two caps complete, will fit from the smallest of children's boots to the largest of gentlemen's.—W. G.



Screw Lasts. Fig. 1.—"Boss" Stretcher. Fig. 2.—Joint Stretcher.

**Violin Bridges.**—CLEVUM.—We are without the address of COMME IL FAUT, who should advertise in WORK.

**Model House.**—H. S. (*Oxford*).—These houses are made of different sizes, but Fig. 1 shows a perspective view of a very common size, with a few of the principal dimensions given. The house itself is principally made of cardboard, the flat piece, to which the house is fastened, being extra strong, and its rigidity is increased by three longitudinal strips of wood ¾ in. wide by ¼ in. thick, one fastened down the centre, the others down the sides. The floor of the house is of wood, together with the two inclined supports and the figures and the ornaments on the roof. The sketch shows about the correct proportions and style of one class of house, which can be altered and ornamented to suit the taste. Thin coloured cardboard can be used for the walls, and painted to imitate stone, brick, etc. The decorations consist of gilt and various coloured stiff perforated papers and paper flowers, which, on account of the limited space in "Shop," I shall have to leave. The size of the house will all depend on the size of the figures used, as if the figures are bigger the openings must also be enlarged, and, for the sake of symmetry, the house also. I have shown in Fig. 1 a part of balcony removed, so that the space between the



Model House and Figures. Fig. 1.—Perspective View of House with Part of Balcony removed to show Platform for Figures.

floor and the bottom of the central partition, *e*, can be seen. It is about ⅛ of an inch, and is left to allow the figures to turn completely round, as well as to rise and fall as the gut contracts or expands. The principal difficulty will be in arranging the figures and catgut, so in Fig. 2 I have shown the arrangement entirely separated from the house. The dimensions of the figures, etc., here given suit a house of the size shown in Fig. 1. Having carved or otherwise obtained two figures, fix them by glue (as this seems to be the principal medium for fastening the parts together) to a flat piece of wood. In the centre of this, or, I should say, so that the figures will balance, place the round upright *a*, in this case 1 in. long by rather less than ¼ in. diameter, with a hole in top for gut, which latter should be about the thickness of the medium string in a fiddle, and is fastened therein by means of glue; before inserting the gut, tie a knot on the end. Do not cut the gut to the length shown in Fig 2, but leave it somewhat longer. Turn a small piece of wood, *c*, ½ in. diameter, and fit it on the roof as shown at *d*, Figs. 1 and 2, and in such a position that a line through its centre passes just behind the pillar *e*, Fig. 1. Bore a hole ¼ in. diameter centrally through it, and turn a small cap and pin, *b*, to fit it easily. Bore a hole centrally through this just large enough for the gut to pass. Having fixed on the top, *c*, place the figures in their respective openings, with the central pin, *a*, behind the pillar, *e*, Fig. 1; pass the gut through the roof and *c*, and then thread it through the cap, *b*. Now place cap, *b*, in position shown in Fig. 2, and gently raise the figures by drawing up the gut till they swing midway between the floor and the bottom of the central pillar, *e*, Fig. 1. Now drive a small wooden peg dipped in glue into the hole where the gut is, and cut off both peg and gut. To prevent the figures moving sideways, form a square shaft by gluing to the central pillar, *e*, internally a piece of cardboard, taking care that the pin *a* is within before gluing it fast. A slight amount of play should be allowed between the pin and sides of shaft, so that there will be no perceptible friction to prevent the figures turning easily. The figures are set as shown in Fig. 1—that is, half in, half out, on some moderate day, when neither wet nor fine. This is done by turning the top of chimney, *b*; probably at first it will need a little bit of attention till the gut gets extended. I hope the above few remarks will be sufficient to explain away any difficulties. It is the want of space only which prevents a thorough description.—P. B. H.

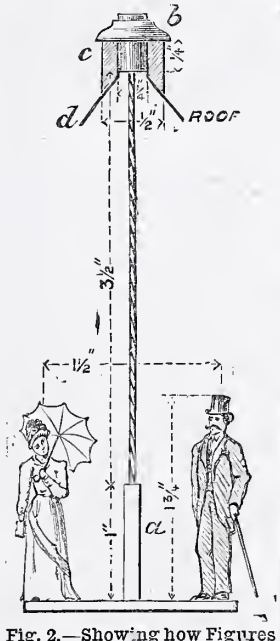


Fig. 2.—Showing how Figures are hung to Gut.

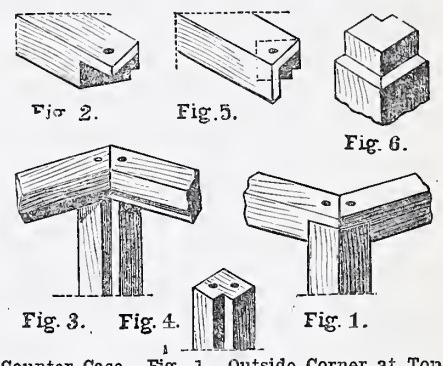
**Shoemaker's Wax.**—J. K. (*Farnley*).—Take 4 ozs. of pitch, 1 oz. of resin, and about a ½ oz. of good tallow, and heat them well on a slow fire in a pipkin or old saucepan (being very careful they do not take fire, as they are very combustible). Stir this admixture till the resin has melted and mixed well with the other ingredients; then pour the whole into a pail of cold water, and when it has got sufficiently cool to handle, put your hand underneath, and turn the edges over to the centre with the other, to make it into one ball. Take it out, and make it into a roll. Take one end in each hand, and pull it out as long as you can without breaking it. Double it, and pull out again and again; the more it is pulled (or worked) the better and brighter it will be. This done, lay it out on a slab, seeing it does not stick. Roll it out, cut it into strips about an inch wide, and cut the strips into pieces about an inch and a half long; each piece is called a ball. Wax has to be made hard in warm weather, and soft in cold. To make it softer, add more tallow; to make hard, use more resin. It is best to make it hard, as it can be made soft *ad lib.* without being again heated—simply by working a little tallow into it. It should always be kept in water to prevent it sticking to anything or together.—W. G.

**Weights of Sheet Metals, etc.**—NO NAME.—Yes, there is such a book; it is called "Engineers' Tables," published by Spon, Charing Cross. It contains, besides the weights of sheet metals, hundreds of other useful memoranda of all kinds, such as weight of hoop iron, chains, nuts and washers, round, square, and flat iron, carpenters' memoranda, bricklayers' and plasterers' ditto, and a variety of valuable information. It is a tiny book, and will go in the vest pocket. Price 1s.—R. A.

**Counter Case.**—H. B. (*Melbourne*).—The corners of your prospective counter case should be constructed after the manner described by the present sketches. As the corners will exactly resemble each other, and as also the bottoms will be similar to the tops, the explanation of one top corner will



Counter Case. Fig. 1.—Outside Corner at Top. Fig. 2.—End of a Top Rail. Fig. 3.—Inside Corner at Top. Fig. 4.—Upright. Figs. 5 and 6.—Alternative Methods of shaping Top and Bottom Rails and Uprights.

be sufficient. A sectionally square upright should be rebated from top to bottom, as in Fig. 4. That part of the upright will face the inside of the case. The horizontal rails will be halved and mitred over and around the block, as in Figs. 1 and 3, and screwed or dowelled there. These rails will be rebated as in Fig. 3. As an alternative method, and one much more difficult, albeit stronger, Fig. 5, as the end of a horizontal rail, and Fig. 6, as the top (and bottom) of the upright, might secure preference. Certainly I should not cut the glass until the wooden portion of the case is constructed. The glass can be fixed in by means of putty, or by sectionally triangular wooden strips glued over them into the rebates. They can then be easily repaired in case of damage. The bottom board could be covered in velvet, and fit within the bottom rebates. It is supposed that a hinged glass lid will bodily cover the top. Drawings are shown free from representations of beads or chamfers, to avoid confusion.—J. S.

**Photograph Enlarging.**—H. J. H. (*Hackney*).—The method of enlarging from ferrotype or other positives is very similar to that of enlarging from negatives. Fix up the picture to be copied in a good light, avoiding reflections, and proceed as in enlarging from a negative. A negative will be the result, and can be printed direct or copied again in the camera, when a positive will result, suitable for bromide and enlargements of that class. The chief difference is in the exposure, an opaque picture requiring rather longer than a transparency. All pictures that have to be copied by reflected light are necessarily produced in a similar manner in one operation if a negative to print from is required, and in two operations if the desired result is to be a developed positive.—D.

**Shoe Gloss.**—SNOBBERY.—No; boot finishers do not put anything into their ink. The cause of the permanent gloss on heels finished by a finisher is the ink which he uses, and the method of ironing afterwards. You should get good American burnishing ink, and add one-third of ordinary shoemakers' ink. Put this on in the ordinary way, and when it has dried to just a nice dark blue (that is not what is generally called "bone dry"), iron up with a warm glazing-iron, or, better still, a double-handled burnisher. It should be rubbed on hard, even, and firm, and with a quick motion. When it is quite bright all over, slightly damp it down, and burnish again. This done, iron on heelball, and then rub it off even with an old cloth. To finish, rub a little whiteball on the cloth, and polish the heel with it. Fake is often used instead of heelball; it is a more ready method, as it is only rubbed on with the finger, and therefore saves the last ironing. It also gives a good polish when used instead of whiteball. To prevent heels cracking, flesh the back and buff off the grain of each piece of leather. Use it when it is only mellow—that is, not too wet or too dry—and do not hammer the heel stuff too hard. Put a little paste on each lift before you put on another, and after the heel is knifed up, properly pare the edge, and never finish till the heel is dry. Rasp each lift to make it rough before applying the paste.—W. G.

**Nails.**—J. C. (*Cheadle*).—Try the large Sheffield nail makers for the nail you require.

**WORK Back Numbers.**—E. H. (*Sunderland*).—The parts of WORK from January, 1891, to May, 1891, price 6d. each, can be had on order of any bookseller.

**WORK Exhibition Certificate Frame.**—N. M. (*Glasgow*) AND OTHERS.—A special article on this subject is not deemed necessary. Any contribution to "Shop," Section I., will be attended to.

**Bicycle Wheels.**—G. P. (*Gloucester*).—The Victor Cycle Co., Grimsby, supply these wheels.

**Turkeys.**—M. H. (*Higher Walton*).—The question you ask is not suited to this Journal. Write to one of the Poultry Journals.

**Umbrella Silk.**—L. B. (*Marylebone, W.*).—A good wearing Union (mixture of silk and wool or silk and cotton) will cost from 2s. 3d. to 4s. per yard; a silk (pure) from 2s. 9d. to 5s.; and can be obtained from Messrs. Morland & Sons, Wood Street, Cheapside, or Messrs. James Ince & Son, 61, Bishopsgate Street Without, E.C.—H. W.

**Violin Making.**—W. W. (*Patterdale*).—You do not enclose stamps, so that the copy of WORK cannot be sent you. Procure the Indexes to Vols. I. and II. through your bookseller. The violin articles are now running through Vol. III.

**Condensing Engine, Book on.**—YOUNG ENGINE DRIVER.—"The Theory and Action of the Steam Engine," by W. H. Northcott, C.E.; 3s. 6d.

**Printing on Tin.**—ANXIOUS.—If this correspondent by "printing on tin" means the decorating of tin, such as the fancy biscuit boxes, etc., I can only say that it is a patent process, and it is not in my power to give particulars of same. Apply to the Tin-Plate Decorating Company, Neath.—R. A.

**Zither.**—J. M. B. (*London, W.*).—The article on how to make a Zither is in the Editor's hands, and only awaits space for publication.—R. F.

**Renovating Chair Seats.**—W. B. (*No Address*).—There is no way of renovating worn leather seats; the chairs must, to make a good job, be re-covered. Any attempt at partial dyeing will make matters worse. The faded leather may, however, be freshened up. Some advise a little French polish to be laid on very lightly, care being taken not to saturate the leather. Some advise white of egg as a reviver; and there is an article sold at shoe and other shops as "kid reviver," which might be used.—S. W.

**Imitation Ivory.**—HARD UP.—I can give methods for home-made imitations of ivory suited merely to decorative purposes, but umbrella handles would need more strength. The best imitation of ivory is, I believe, "ivorine," and this, probably, would be the thing for HARD UP. But he will have to get it from the makers, the British Xylonite Company, 124, High Street, Homerton, E. It costs 4s. or 5s. per lb., and works easily.—S. W.

**Leclanché Cells.**—A. C. (*Croydon*).—It would be well for you to advertise your prices, with name and address, in the cheap "Sale and Exchange" columns of WORK.

**Silent Gas Engine.**—A NEW READER.—The gas engine is rendered silent by the system of compressing the charge before exploding it, and the compression gas engine has not been treated in WORK. Your non-compression engine should give out more than one man-power if of 5 in. diameter and 11 in. stroke; a cylinder of that size on the compression system would be much more powerful, because by compressing the charge the gases burn slower and more gradually; instead of a sudden kick at the crank-shaft, as in yours, you get a longer push. To convert your engine would be very difficult, if not impossible.—F. A. M.

**Binding WORK.**—NED.—You should write upon this subject to the publishers, Messrs. Cassell & Co., Limited, Ludgate Hill, London, E.C.

**Bamboo.**—A. M. S. (*Westminster*).—The firms named below deal in this article:—F. Westbury, 183, Great Dover Street, S.E.; Benjamin & Co., 168, Great Dover Street, S.E.; W. and T. Elmore and Sons, 16, City Road, E.C.; and S. J. Eaton & Co., 3, New Inn Yard, Tottenham Court Road, W.—M. M.

### III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Inking Roller Composition.**—C. D. (*Glasgow*) writes:—"I should be much obliged for any instructions as to how to make a small inking roller, including composition of 'dolly,' to be used for inking woodcuts."

**Rubber Balls and Balloons.**—Z. Z. Z. (*Wednesbury*) writes:—"Will any reader kindly tell me how to make toy indiarubber balloons and indiarubber balls?"

**Steam-Ship "Sarah Sands."**—W. W. (*Canning Town*) writes:—"Will any kind reader, or seafaring one that may have been aboard the S.S. *Sarah Sands*, which was destroyed by fire, inform me where I can obtain a book of the above-named ship that speaks of the bravery of Fireman Woodward?"

**Hydraulic Lifts.**—ANXIOUS writes:—"Would any reader be kind enough to explain the system of the working of hydraulic lifts, etc.?"

**Carpenter's Bench.**—R. S. D. (*Edinburgh*) writes:—"In the number of WORK for October 4, 1890, page 471, under the heading 'Carpenter's Bench,' E. D., in reply to J. B. F. (*Brixton*), describes a bench, and states that it can be obtained for 30s. I should be glad if he could inform me where; also whether a considerably smaller one, with thinner top, could be got for £1."

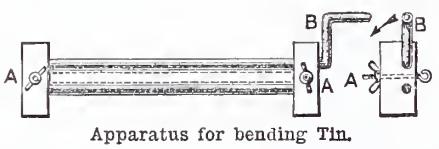
**Ink Blots.**—INKY writes:—"Can anything be made to get out marking-ink blots or names in linen?"

**Tricycle.**—W. R. (*Mile End*) writes:—"Will any reader kindly inform me how to make a tricycle to work with my hands? I want it with a place to convey toy goods in, as I am lame."

**Umbrella Fittings, Negatives, etc.**—CONSTANT SUBSCRIBER writes:—"Will any reader tell me a place where I can get umbrella fittings with which to do jobbing work, repairs, etc.? Also I should be glad to know of a method of getting rid of rain stains on negative caused by getting wet during exposure. I have got silver stains off, but rain stain spots remain."

### IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Hoop Rollers.**—A. H. L. (*Higher Bebington*) writes, in reply to A. L. (*London*) (see page 91, No. 110):—"A cheap apparatus for bending tin, etc., might be constructed as follows: Take three pieces of iron pipe 1½ in. diameter. To one of these attach a handle, and place it with one of the others, 2 in. from each other, on or in a wooden frame, so that the ends rest on or in bearings, so that they may revolve easily. The third piece of tube should be



Apparatus for bending Tin.

plugged at the ends, and axles formed, of such size as to work in the eyes of eye-bolts, having a nut on the end of each, as in diagram. To work, place the edge of the sheet over the middle roller (piece of tube) and under the other two; turn the wing-nuts till sufficient curve has been obtained, and then draw the sheet through between the rollers, turning the handle (B) in the direction of the arrow."

**Air Cushion.**—E. L. (*No Address*) writes, in reply to H. R. (*Clapham*) (see page 222, No. 118):—"Fill the cushion with wind, and put it under water. You will soon find out by bubbles where the hole is. It depends what material it is made of before I can say what to repair it with, but should think indiarubber solution. Prout's glue is of no use: it cracks."

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—G. S. R. (*Tewkesbury*); THE GOLDSMITHS' CO.: O. B. (*Preston*); W. H. K. (*Accrington*); T. R. H. (*Manchester*); A. S. (*Rotherhithe*); J. N. (*York*); W. J. T. (*Cardiff*); J. E. W. (*Burslem*). G. F. C. (*Southampton*); T. W. B. (*Leicester*); W. M. (*Derby*); STRIKE-A-LIGHT; H. M. (*Liverpool*); READER OF "WORK"; N. H. (*Huddersfield*); H. J. M. (*Bristol*); F. I. (*Highbury Grange*); A NEW READER; J. G. (*Glasgow*); T. R. E. # A WONDERFUL MEDICINE.

# BEECHAM'S PILLS

Are universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, and all Nervous and Trembling Sensations, &c. &c. The first dose will give relief in twenty minutes. This is no fiction, for they have done it in countless cases. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

**Worth a Guinea a Box.**

FOR FEMALES THESE PILLS ARE

"A priceless boon, a treasure more than wealth; the banisher of pain, the key to health."

These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the nervous and debilitated is,

***BEECHAM'S PILLS have the Largest Sale of any Patent Medicine in the World.***

Prepared only by the Proprietor, T. BEECHAM, St. Helen's, Lancashire, in Boxes 9½d., 1s. 1½d., and 2s. 9d. each. Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

## AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their Improved Eclipse Cameras and Outfits, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above: also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge

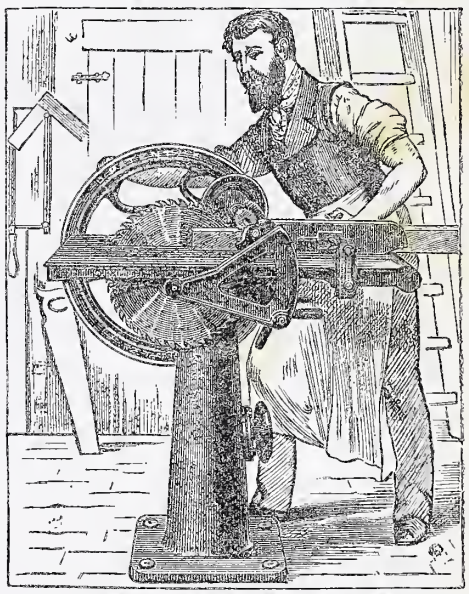
**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra. These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.,** post free.

*A Wholesale Dealer's Stock-in-Trade at about Half-Price.*

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

**J. H. SKINNER & CO., Manufacturers, W Department, EAST DEREHAM.**



**"THE LEYTON"**

New Patent Circular Saw Bench for Hand Power.

Cuts Tenons, Mitres, Grooves, Rebates, and Saws Wood 3 inches thick with ease.

LEWIS & LEWIS, *Engineers, Wandsworth Bridge Wharf, Townmead Road, Fulham, S.W.*

## FRETWORK FOR AMATEURS

OF BOTH SEXES AND ALL AGES.

The most Fascinating and Profitable of all Home Pastimes

250,000 Fretwork Designs, 100,000 ft. Solid & 3-Ply Fretwood Veneers, etc., 1,000 gross Fretsaws, etc., always in Stock.

**To Beginners—A Complete Outfit, 2s. 6d., post free.**

Comprising 12 in. Steel Frame, 24 Saw Blades, Awl, File, 3 Designs, with sufficient planed Fretwood, and full Instructions. 6 ft. assorted planed Fretwood, 2s. 6d.; 12 ft. ditto, 4s. 3d., post free. Book containing 12 sheets full-size Designs, 1s. Fretsaws, 1s. 4d. per gross.

New Catalogues of Machines, Designs, Wood, Tools, etc., with 60 pages and 600 Illustrations, and full instructions for Fret-cutting, Polishing, and Varnishing, price 4d., post free. A Specimen 6d. Fretwork Design SENT GRATIS with each Catalogue; also a List of Designs, Outfits, Tool Chests, etc., at Greatly Reduced Prices to clear. N.B.—All orders MUST be accompanied by remittance Apply—**J. H. SKINNER & CO.,** Manufacturers of Fretwork Materials, **W** Department, **East Dereham, Norfolk.**

*Kindly mention this paper when ordering.*

**CASSELL'S CLASSIFIED CATALOGUE,** containing particulars of upwards of ONE THOUSAND VOLUMES published by Messrs. CASSELL & COMPANY, ranging in price from **THREEPENCE TO FIFTY GUINEAS,** will be sent on request *post free to any address.* CASSELL & COMPANY, LIMITED, *Ludgate Hill, London.*

## "The Amateur."

Pattern Sheets of Fret, Carved, and Inlaid Work; Painting on Wood, and other Similar Domestic Arts.

*Terms of subscription:—*

*5s.* per annum; *2s. 6d.* half-yearly; or *6d.* monthly, of all booksellers.

*Complete Catalogue Nos. 38, 39, & 42, of Artistic Fretwork, Carving, Inlaying, and Wood-Painting Designs, Machines, Tools, Mouldings, Cabinet Fittings, etc., with 1,500 Engravings, 6d.*

Having more than a million customers in England and the British Colonies, books sellers will not only find it easy, but also remunerative, to push "The Amateur" wherever the English language is spoken.

## A FULL-SIZE DESIGN FOR DISH, ETC., IN REPOUSSÉ WORK.

BY J. EADIE-REID, GUILD OF HANDICRAFT.

THE art of beating up metals—such as silver, brass, and copper—is perhaps one of the most beautiful of our handicrafts, and it is with pleasure we see a demand rising in our English market for this work. It is capable of the most varied of treatments—delicate as only the artist hand knows how, yet simple and broad as the most daring.

The technique of repoussé work has been described in Vol. I., so that it only remains for me to touch but lightly upon this side of the subject. Having already made a careful drawing of the design with which you are to ornament your plate, it would be desirable to pounce your sketch, and by this means transfer its lines to your sheet of copper. At this stage go over your lines carefully with Brunswick black or ink. This will enable you to handle your work fearlessly, and will lessen the danger of lost lines and temper. Then begin to chase the outline, taking care not to cut your metal in this fashion, V, but rather make an indentation thus: U. This, if rightly executed, will have marked your design firmly upon the reverse of the plate. Putting it upon its face, you can beat from the back until you have raised it sufficiently on the front to enable you to model with freedom. Having got your ornament into an advanced state, you must proceed to hammer the plate into its concave shape before finishing. This is done by laying it upon a bed of pitch, and beating steadily with the hammer.

The degree of delicacy of both labour and design can only be determined by the metal which you have under your hand. The design which I have made for you would be suitable for copper, while for work of a more dainty finish silver would be preferable. An hour spent amongst the beautiful examples of repoussé work in the South Kensington Museum will be of more use to you than any words of mine on the subject.

As to design: let it be vigorous, and tell its purpose in as few lines as possible, and above all things—be it plate or sconce, whatever you may have set your heart upon beautifying—do not let your ornament cry out at you, and thrust itself forward; let it rather accentuate the principal lines, give richness to the spaces, and always be decorous.

## THE KALLITYPE PHOTOGRAPHIC PRINTING PROCESS.

BY L. IVOR POOLE.

CLAIMS — SIMPLICITY — ECONOMY — RAPIDITY — APPEARANCE OF PRINT—MARGIN—STAINING FINGERS — DRYNESS — OVER- AND UNDER-EXPOSURE—PRINTS FROM THIN NEGATIVES—BROWN COLOUR—CHEMICAL ACTION.

ONE of the simplest photographic printing processes is that which forms the subject of the present article. Simplicity, however, in any new process is not in itself sufficient to entitle it to adoption, for no one should grudge a little extra work to ensure better results by some other means. Although comparatively new, the kallitype process has been introduced sufficiently long to enable one to judge of its qualities. There are few of us who care to take more trouble than necessary to ensure good results, either in our pursuits of matters of business or as pastime, so that when a really good process is brought forward we cannot do less than welcome it. For some time past I have been trying kallitypy, and think, perhaps, my experience may be of use to some of our readers by calling their attention to the process. As stated above, it is simple; it is also cheap and quick—not so rapid as bromide, but more so than the ordinary albumenised paper. I will take up these qualities in the order stated.

*Simplicity.*—The printing is done in an ordinary frame in the usual manner, by daylight, for the paper is not sensitive enough to be used with artificial light, like bromide. The print, which only becomes faintly visible by exposure, must next be developed; and this can be done after any interval, if they are kept dry in the dark. The development is effected by floating them face downwards for a few seconds in a solution formed as follows:—Nitrate of silver, 50 grains; citrate of soda, 1 oz.; bichromate of potash, 1 grain; water, 10 ozs.; ammonia ·880, ½ dram. This solution is used cold, so that the necessity of keeping it to a certain temperature, as in the older platinotype process, is obviated. The print rapidly develops—as stated above, in a few seconds—and is then placed face upwards on a clean piece of glass, a plate, or anything of the kind, for a minute or two, during which the print gains in brilliancy. A washing solution of the following is then used:—Kallitype developer, ½ oz.; citrate of soda, 2 ozs.; water, 20 ozs. In this the print is immersed for, say, twenty minutes, for considerable latitude is allowable, and then removed to another washing solution made of citrate of soda, 1 dram; ammonia ·880, 2 drams; water, 1 quart. This should be divided in two portions to form two separate baths, the final one of which should be renewed as soon as it assumes the slightest tinge of yellow, when it may be used as the first one of this washing solution, or be added to it. The third washing bath is for the purpose of thoroughly completing the chemical process undergone during development. The print, after being in this solution for twenty minutes, or, say, ten minutes in each bath, is finally washed in clean water for a few minutes, after which it only requires to be dried.

*Cheapness.*—The expense is inconsiderable, either for the paper or the chemicals. The former can be had cut to the usual sizes or in the full sheet, measuring 26 in. by 20 in., costing from 9d. to 10d. per sheet, according to the number purchased. Cut, the paper ranges in price from 9d. for full quarter-plate size, to 2s. 6d. for whole plate per two dozen package. For purposes where cost is of more consequence than quality, a cheaper paper is supplied at 12s. per quire of full-sized sheets. This make is recommended when large numbers, as for advertising purposes by manufacturers, are wanted; and I have seen some really excellent work done with it, though it is not to be compared with the better quality for ordinary photographs. The chemicals are both inexpensive in the first cost and economical in use, sufficient of the salts to make 10 ozs. of developer being purchasable for 1s. 3d., while the cost of the washing solutions is merely nominal. The greatest point of economy, however, lies in the fact that all the solutions can be used over and over again, and will serve for a large number of prints. By degrees the developer gets exhausted, but may be renewed by adding two grains of nitrate of silver for every ounce of the solution. The first washing bath is usable so long as it removes the yellowness from the prints, and the others should be fully charged with ammonia, and are efficacious, as has been stated, till the final one becomes tinged with yellow. It will thus be seen that there is no toning bath required, so that the costly material known as chloride of gold is dispensed with.

*Rapidity.* — Although printing is more rapid than ordinary sensitised albumenised paper, I must confess that I do not find it so rapid as it is sometimes said to be. Whether, scientifically, six times the rapidity of ordinary albumenised paper, as it is stated to be, I am not able to say; but, so far as my experience goes, the degree of extra rapidity seems to increase in ratio according to the light. That is to say, the speed, comparing it with albumenised paper, is not so great in a dull light as in bright sunshine. In a poor light the extra sensitiveness of the paper is by no means so marked.

The chief point in respect of speed is the short time in which a print can be completed, for it is quite possible to develop, wash, and dry a perfect one in three-quarters of an hour; while if only a rough proof is wanted, it can be ready in very considerably less, as the time occupied in washing may be reduced to a few minutes.

*Appearance.*—The prints are a fine black, very much resembling those produced by the bromide or platinotype processes; and, provided the right exposure be given, which is very easily learned, it is almost impossible to fail—provided, of course, that due care is taken with cleanliness and purity of chemicals. The surface is a matt one—*i.e.*, the prints are not glossy.

By using masks, a white margin may be left round any photograph, which can be written on easily as ordinary writing-paper, thus affording a ready means of writing titles, etc., on them. It may further be noted that the prints do not curl, but dry flat; so that by having them with a white margin, mounting may in many cases be dispensed with.

As against the manifold advantages connected with the kallitype process, is the fact that in working it the developing solution is apt to stain the fingers to such an extent as to remind one of the days of wet-plate photography. To avoid this, indiarubber finger-stalls or a pair of pliers, or something convenient, should be used to lift prints in and out of the developing solution. Without some such appliance, it is almost impossible to prevent the finger-nails being stained.

The paper should be kept dry both before and during exposure, as well as during any interval prior to development; otherwise it is difficult to determine whether the exposure is correct, and impossible to get a good colour. I have not, however, found that the paper is particularly susceptible to damp, so that no extraordinary precautions, such as keeping it in calcium tubes, are necessary. If it should be damp, it may be dried by the fire before exposure; but this should be done carefully, as if the paper is made too hot, the subsequent print may be "fogged." Over-exposure should be carefully guarded against, as it is impossible to counteract ill-effects from this cause, the resulting print being "mealy" in appearance or muddy-looking, and very apt to show stains and markings. Under-exposure may, to some extent, be overcome by prolonged development. The best results are naturally got from good negatives; but if these are thin, the prints may be remarkably improved by the addition of bichromate

of potash to the developer. A very small quantity only is necessary.

It is not necessary to develop, etc., in the "dark" room, but certainly the operations should not be done in bright daylight, more care, if anything, being required than with albumenised paper.

Should the print be of a sepia or brown colour, instead of black, it is probably owing to an impure citrate of soda having been used; but if there should be any difficulty in obtaining it, a suitable quality can be had from the manufacturers of kallitype paper.

A not unimportant matter in connection with prints made by this process is that they are considered permanent.

Such, in the main, are the chief features of kallitype and its working; but perhaps a few remarks on the chemical changes on which it is based may not be uninteresting; and for these particulars I am indebted to the courtesy of Mr. Lewis, the founder of the Birmingham Photographic Company, Limited, who manufacture the paper. The paper is sensitised by ferric oxalate. The action of the light changes this from a ferric to a ferrous salt. During development the processes are somewhat complicated, and may be briefly explained thus. The ferrous oxalate is dissolved by the citrate of soda, which enables it to reduce the nitrate of silver, and prevents the precipitation of iron by the ammonia. This is required to dissolve the citrate of silver which is formed by the nitrate of silver and citrate of soda. On floating the paper on the developer, metallic silver in the form of a black powder, which forms the picture, is precipitated. The bichromate of potash assures contrast, and being a very powerful oxidiser, is used in very minute quantity, for in excess it would dissolve the half tones. The final baths, in which ammonia is the principal chemical agent, fix the prints, and if this is not done thoroughly, it seems hardly necessary to say that discoloration will speedily ensue. With this *résumé* of the chemical actions involved, my remarks must be brought to a close. It may be well to add that the process has been considerably improved on since it was introduced in the early part of last year; and that, bearing in mind the demands on the "Shop" columns, it will be as well for those who meet with difficulties or want further information about kallitype to apply direct to the manufacturers. Their address is 99 and 100, Gladstone Road, Sparkbrook, Birmingham.

## THE SAFETY BICYCLE: ITS PRACTICAL CONSTRUCTION, ETC.

BY A. S. P.

FITTING BEARINGS ON BOTTOM BRACKET—FITTING THE CRANKS—TURNING AND FITTING REAR FORK ENDS—TURNING AND FITTING STEERING BARREL AND TUBE—FITTING FRONT FORKS—HANDLE-BAR, ETC.—CENTRE BRACKET—CUTTING THE TUBES TO LENGTH.

WE have now to look up the illustrations accompanying these papers in page 168, in order to find the parts of our machine requiring turning and fitting. Suppose we take the bottom bracket casting (Fig. 4, page 168). We have first of all to get a pair of knuckle-joint ball-bearings, which may be Bown's or Rudge's, or the Birmingham small arms' make, which are the cheapest of the three. The forks in the lower end of the bracket have to be filed out to fit the knuckle-joint. (See Fig. 4B.) To file them both straight and true with each other, they should be finished with a long flat file, and both at once, to ensure their being true, so that the two bearings will, when fitted, be truly parallel with each other; as, unless they are so, when the axle is inserted it will only run freely in the bearings if they are truly set in line. The knuckle-joint should fit the fork tightly and without shake, as, apart from the unpleasantness of pedalling with loose, shaky bearings, the shaky movement twists the shaft in the bearings at every stroke, and in a very short time destroys them. The bearings neatly fitted, bolt-holes must be bored through the jaws of the fork to carry the bearings. These are usually $\frac{5}{16}$ in., and require to be very accurately bored, in order to meet the hole in the knuckle-joint, which must not be tampered with in any way. As the forward ends of the rear tubes are bolted to the back of this bracket, it is necessary to file the back edges quite true, as also the face of the cross-plate on the end of the rear tube. This plate is also bored with $\frac{5}{16}$ in. holes, for bolting on; the lower end is held by the bolt that holds the bearing, and the upper end by a similar bolt passing through the fork at the semicircular projection.

The two sockets on the top have to be bored or reamed out to fit $1\frac{1}{8}$ in. tube. This done, the whole bracket is filed up neatly; and at this stage the pedal shaft should be fitted.

The pedal shaft is a piece of round $\frac{3}{4}$ in. steel; $7\frac{1}{2}$ in. long over all. It is turned for bearings and cranks, as shown at Fig. 16. The central part, which is $\frac{3}{4}$ in. thick, is $4\frac{1}{4}$ in. long; on this part, as indicated at W, the chain-wheel is keyed on. A good long flat, at least $\frac{3}{8}$ in. broad, is made on the $\frac{3}{4}$ in. part of the shaft, and a key-slot in the boss of the wheel, with a key of steel well fitted. The chain-wheel is to be keyed on the shaft, exactly in line with the cog on the rear wheel hub; and, of course, this cannot be done till that wheel is in its fork. Meantime, fit the two sleeves of the ball-bearings (see Fig. 16) on to the parts marked B, B on the shaft. These sleeves, which should have a $\frac{11}{16}$ in. hole, have each a small flush set-screw, which enters a small hole in the shaft. Of course, these two sleeves must be placed on the shaft, so that when the balls are inserted the cases will hang parallel in the bracket, and the shaft turn freely when the bearings are adjusted. The parts C, C are reduced to $\frac{5}{8}$ in. for the cranks, the boss of which is usually $\frac{3}{4}$ in. through the hole. The cranks should be bored first, and the shaft ends turned to fit. Now, cranks may be keyed on hard and fast, or they may be detachable. Keyed-on cranks are cheapest, but they have a nasty trick of coming loose when not wanted to. They have also a nasty trick of resisting every attempt to get them off when wanted. (For keyed-on cranks, see Fig. 17.) A flat is made on the parts C, C on opposite sides of the shaft; then cranks are slotted, and keys fitted same as for the chain-wheel. In detachable cranks (Fig. 18), a pin with a nut passes edgeway through the boss end of the crank, as shown; the hole bored for the pin cuts a piece out of the shaft. After the hole is bored it is made taper, and a taper pin fitted; this pin is often flat on one side, and a flat filed out of the shaft to fit. When a crank of this sort becomes loose the pin is simply drawn in, and the nut takes and keeps it up; by removing the pin, the crank may be readily taken off; hence its name, "detachable."

If the cranks are bought as rough stampings, they have got to be bored for shaft, slotted or bored for keys, filed out in the long slots for pedal-pins, then finished up and polished for plating.

Now we will lay this bottom bracket aside, to be taken up when the tubes are fitted and brazed.

Fig. 6 (page 168) is the fork end for the rear wheel. The one shown is that for the left side, having the extension for the step. The hole for the step is tapped $\frac{3}{8}$ in. The centre hole for the adjusting screw should be bored and tapped $\frac{5}{16}$ in., and a square-headed pin fitted; this pin is 2 in. long. Now the tenons A and B are turned: A to fit inside $\frac{3}{4}$ in. tube, and B inside $\frac{5}{8}$ in. tube. The shoulders should be cut square in, so as to ensure a good joint when the tube is fitted. These parts may now be laid aside, as they will require to be filed up after brazing, and the screw-holes cleaned out with the taps.

Fig. 7 (page 168) is one form of step which is commonly used. A rubber step would simply have a $\frac{3}{8}$ in. pin about 2 in. long, and a foot-rest rubber put over it with a $\frac{3}{8}$ in. nut on the end.

We now take the steering barrel (Fig. 8, page 168) in hand, with the front fork crown. The two ends of the barrel have got to be coned out in the lathe. For this purpose it is mounted on a mandrel, like Fig. 19. The ends of the mandrel are reduced to $\frac{5}{8}$ in., to allow a side-cutting tool to work in making the coned parts. The cones are made to an angle of about 60°. This done, the outside of the barrel is turned on the same mandrel, all but the parts where the projecting sockets interfere. Opposite these the file must be used. The two sockets are now cleaned out to fit $\frac{1}{8}$ in. and $\frac{5}{8}$ in. tubes respectively. Then the inside of the barrel is reamed or bored out, to allow the 1 in. tube to pass up easily. This 1 in. tube, called the "steering tube," has got to be fitted to the top of the fork crown, A (Fig. 8); and from the abutting shoulder of the tube the coned part falls away, as shown. This is of the same angle as that in the barrel, so that the one will fit neatly on the other. The crown piece may have a $\frac{5}{8}$ in. hole bored through its centre to lighten it, or a $\frac{3}{8}$ in. hole may be bored and tapped for a screw to fix the mud-guard. This hole must be bored and tapped before the forks are brazed on. These may now be fitted to the two tenons, B, B (Fig. 8), on the crown piece. These should be fitted without shake, and to fill the forks all round, else they will not be good brazing joints. The forks have to be pinned on with $\frac{3}{16}$ in. wire pins, or screws of the same thickness, which are sold for the purpose. But before pinning them on, the lower ends of the forks should be prepared for the front wheel axle, or pin. First of all, the two forks should be made exactly one length, and that length to allow 1 in. clear between the rubber tire and the fork crown, as this is the space required for the brake-spoon. A common practice with hollow-front fork ends is to squeeze them, shut in a vice, and bore the hole for the shaft through the two thicknesses. This is a slipshod method, though it is done by good makers. A better plan is to have solid ends, as Fig. 20, brazed into the fork ends. These are $\frac{1}{4}$ in. thick, and the holes for the screwed parts of the shaft are $\frac{1}{2}$ in. These two solid pieces when brazed into the forks have to get a little set inwards, to be parallel with each other where they abut on the hub ends. The fork ends should be nicely filed up after brazing, and the axle holes bored before they are pinned on to the crown piece.

Returning to the steering tube, which is 11 in. by 1 in. outside diameter, we have to fit a ring or collar, C, coned to fit the upper part of the barrel. This ring is ¼ in. thick, and stands ½ in. above the end of the barrel. A small flush set-screw is put in for adjustment, which presses against the side of the tube, without any perforation to receive the point, which should be blunted or flattened off. On the upper end of the steering tube the lamp-bracket collar is fitted and brazed. This serves a double purpose, as it has the binding screw behind and the lamp bracket in front. The adjusting screw in this is $\frac{7}{16}$ in., tapped. The handle-bar tube, a part of which is shown in the figure, is 8 in. long, and should pass freely inside the inch tube, though without shake. Inside this ⅛ in. extension tube a piece of ⅞ in. tube should be driven, so that the two thicknesses may the better resist the pressure of the set-screw. Sometimes the extension piece is made solid for this reason. The handle-bar T-piece is a stamping or casting (see Fig. 21), with a hole bored horizontally to admit a ¾ in. handle-bar. The tenon A is turned to fit inside the ⅞ in. extension tube. This tenon is about 1 in. long. It takes 32 inches of ¾ in. tube to make a handle-bar. They are now made of many forms and twists, some of them remarkable only for their ugliness. I usually make the handle-bar as in Fig. 22, with a rather sharp turn at B, B, 8 in. from the ends. The horn handles take up 4 in. of this. The T-piece must be fitted on before the second bend is made, as it cannot be put on afterwards. After making one bend, draw it on a board with pencil, and make the second bend to fit the drawing. The T-piece should, of course, be placed in the centre of the straight part, and it must be set before pinning at an angle to fit the steering tube, as in Fig. 1 (see page 33), where it will be seen that the bar is level to within an inch of the horn handle, when it is bent downwards, allowing a more natural grip of the handles. In plan, however, the bar looks as if straight after leaving the bends, as in Fig. 22. The handle-bar, with its extension piece, should be finished up and polished for plating before the horn handles are put on. If the lamp-bracket collar, above referred to, is neatly fitted to the tube, and two small flush screws, one on each side, inserted to bind it to the tube, the brazing may be dispensed with, and the bracket can then be plated, which adds considerably to the appearance of the machine. The adjusting collar, C, is also plated.

We now turn our attention to what may be called the centre-frame bracket (Figs. 9 A, 9 B, page 168). To this part we have no less than four tubes attached, as well as the L-pin and its binding screw. The part containing the L-pin is vertical, the L-pin hole ⅝ in. and the metal surrounding it $\frac{3}{16}$ in. The upper projection is the socket for the upper tube of the frame that runs forward to the steering head. The lower projection is simply a solid part, through which a ⅜ in. hole is bored, and tapped $\frac{7}{16}$ in. for a set-pin to bind the L-pin. The part of the bracket drooping away from the L-pin socket has the eye or socket for the bent tube 1⅛ in. diameter. On the sides of this are the two long sockets for the rear tubes, ⅞ in. diameter. (See Fig. 9 B.) S S is a full-size section of the central part of the bracket. This is a part of the machine that cannot be bought of any of the makers or dealers in this form; consequently, a pattern has got to be made, from which any number may be cast in malleable steel—or cast steel, as it is called. For the benefit of those who would prefer to buy all the parts without troubling about pattern making, I here show (Fig. 23) a bracket for this part of a diamond frame. This is used by several makers in lieu of Fig. 9. It is bought in the rough, and the tenons turned to fit the frame tubes. The two rear tubes join on to it by a bolt passing through an eye on the end of each tube, and through a corresponding lug on the rear of the bracket. (See A, Fig. 23.)

With regard to the bottom bracket above described (Figs. 4A, 4B, page 168), the same objection to pattern-making may obtain. There are quite a lot of styles of bottom ball bracket in the market, from which our cycle-maker may choose, if he refuses to face pattern making. Being a pattern maker, the thing offers no difficulty to me, and I show in these papers my own designs of certain parts, which, of course, have got to be made from patterns not being in the regular market. The fork-bottom bracket, as shown, is my own; and I am satisfied that while it may not be the best, it is much better than many in the market.

Several of the dealers in cycle material issue elaborate catalogues, in which most of the parts are illustrated, and from which the buyer sees what will suit him, there being generally a variety of patterns of the same thing. I should, however, advise our cycle maker, if he is anything of a mechanic, to make all he can make, else he will hardly be able to say he made his machine.

I have now gone over most of the parts of the frame, except tubes and brake work.

The parts here treated being finished and placed in position upon the full-size drawing, the exact length of all of the tubes will be readily measured. The tubes, being cut to the proper length, are to be filed dead square on the ends: this is done with the tube caught upright in the vice. A small engineer's square is used to the ends when filing. The square is applied at three or four different places round the sides of the tube, with the blade across the end. In this way all the tube ends are treated that abut on a shoulder on the solid connections. Those, however, that enter sockets need not be squared on the ends. All tubes that are to be brazed into socket should have an inch or so on the *outside* cleaned with a file; likewise all tubes that have tenon pieces entering them, such as those squared on the ends, should have an inch or so of the *inside* filed clean. This is done that the brazing metal may take proper hold. These connections, moreover, should be kept quite free from dirt or grease. All brazing joints have got to be pinned—that is, small holes must be drilled through all junctions of tubes and solids. If plain wire pins are used, it is best for them to pass quite through both sides, and rivet at the ends, as a plain pin through one side only is apt to drop out while in the fire. Most makers use small $\frac{3}{16}$ in. screws for holding the parts, called "brazing screws." Being screwed in, they do not drop out. The object of this pinning or screwing is to prevent the parts of the frame moving in their sockets while in the fire; as, though they may be tightly fitted, they soon get loose under the heat, and, having been set

rue to square before pinning, it is very lesirable that they should remain so.

I fear I have given many of my readers rouble by referring them to diagrams that ıave appeared in preceding chapters. I am orry to have done this, but it will, I think, ›e perfectly clear to them that it is a case ›f necessity. The repetition of figures ılready given could not be expected, as he adoption of such a course would involve he sacrifice of much valuable space, and, n consequence, there was nothing left for ne to do but give references, so that the liagrams may, at least, be easily found.

The "Loop" or "Bend" Shortening (Fig. 55) is the simplest of these. The rope is merely bent as much as is required, so as to form two bights, and the two parts seized together with small stuff. This is a simple and good method of shortening ropes.

The "Chain Knot" (Fig. 56) is another method of shortening ropes. In commencing it, we make a running knot (Fig. 57), and then draw a portion of the part A through the loop B; this is done with the forefinger and thumb of the left hand. It will now form another loop, through which a fresh piece of A is to be passed. This process is to be repeated until all the slack of the rope is taken up. There are two ways of finishing it off: either by putting a piece of stick or belaying-pin through the last loop, or by drawing the end itself up through the bight.

The "Twist Knot" (Fig. 58) forms another handsome shortening. In commencing, we place the cord to be shortened as in Fig. 59. One of the outside parts is then brought over the middle strand, and the outer strand on the opposite is brought over this, which is now the middle part. This is continued as long as required, the outside strand alternately being placed over the centre strand, as in an ordinary three-plait. Fig. 58 shows the plait completed, and the way of finishing off the end. These shortenings are ornamental as well as useful. Among other purposes, they may be used for thickening a piece of small cord, so as to give more substance where it has to be hauled upon, and thus prevent the hand being cut with the cord.

Fig. 60 is the "Sheepshanks" or "Dog-shanks"—a very old-fashioned method of shortening, and one that is a good deal used, as it is applicable to any size of cordage. The twist and chain knots are not suitable for very stout rope. Two bights are formed in the rope, as in Fig. 59; a half hitch is then made at each end, and slipped over the bights. This is made more secure if a seizing is put round the two parts, at A and B. It can also be secured when ends of rope are free by passing each end through adjoining bight, as shown in Fig. 61.

Fig. 62 is a "Knotted Sheepshanks." This is very similar to the last, the only difference being that the ends are fastened in a rather different way. The two bights are made as before, and each end, after passing through the bight nearest to it, is put through the bight it has just made, thus forming an overhand knot at each end.

## KNOTTING, SPLICING, AND WORKING CORDAGE.

BY LANCELOT L. HASLOPE.

### Shortenings.

Bend Fastening—Chain Knot—Twist Knot—Sheepshanks—Sheepshanks Fastened, Knotted, and Toggled—Knot Shortening—Double Chain Knot.

It frequently occurs that a rope is too long for the purpose for which it is required, and as it would be inadvisable and wasteful to cut it, some method of reducing its length had to be devised; hence arose what are termed "Shortenings."

In making Fig. 63, the parts of the rope are arranged as before. A marlinespike hitch is made at each end, and the bight put through it. The left side of the figure shows the knot made, and the bight in the act of being passed through it. It goes over the outside strand, under the centre one, and over the next. On the right side of the drawing the loop is shown in its place, ready to be hauled taut.

The "Boat-Knot" Shortening (Fig. 64) is another form of Sheepshanks. In this the ends are secured by bringing a portion of the loose part of the rope through the bight at each end, and toggling it with a belaying-pin or piece of wood, as in the Boat Knot. This has the advantage of being loosened very readily. This can be made when both ends of the rope are fast.

The "Knot" Shortening (Fig. 65) is a ready mode of taking up the slack of a rope, though it is not suitable for very stout ropes. It can only be made, however, where one end of the rope is at liberty. The rope is laid as at Fig. 67. The three parts are then grasped with both hands near the bights, and an overhand knot is formed with the whole of the strands. It forms a good shortening for moderate-sized cordage, where the strain is not too heavy.

The "Double Chain Knot" (Fig. 66) is perhaps the most ornamental knot of this group. A turn is first taken round the standing part, and the loose end is then passed through the loop thus formed at A. In doing this another loop (B) is made, through which the end is brought. The end is thus continually passed from one side to the other through the preceding loop until the knot is of the proper length. It may be finished, if required, by making an overhand knot with the end over its own part, or merely passing it through the last loop, and hauling on it.

## THE MAINTENANCE OF A TRUE HORIZONTAL AND LATERAL POSITION IN DRAWERS WHEN PULLED OUT TO THE FULLEST EXTENT.

BY THE INVENTOR.

DROPPING OF DRAWERS WHEN DRAWN OUT—MODE OF PREVENTING THIS—NATURE OF INVENTION—FLAPS—HOW AND WHERE FIXED—ADVANTAGES OF INVENTION—CASES IN WHICH INVENTION IS SPECIALLY APPLICABLE.

IT is well known that drawers, however well made, are very liable to, and usually do, stick when being pushed in, unless during such operation they are held in a true position. For instance, when drawers, as at present constructed, are drawn out more than half way, they invariably *drop*, so that to enable such drawers to be easily pushed in (when out for more than the distance referred to) it becomes necessary to raise the drawers at the time of pushing them. It is also necessary to apply the pushing force centrally. For instance, in drawers as at present constructed, should they be provided with two handles, they often stick if only one handle be used.

The inventor claims that a drawer, when constructed with the following simple improvements (for which a patent has been applied for), may be drawn so fully out that the *back* of the drawer may be flush with the front of the cabinet, and that drawers when so drawn out can be moved in again with the greatest ease, however carelessly pushed. Nor is it necessary that care should be observed in the pulling out of the drawers, as a stop should be fixed to prevent their being pulled out altogether.

The invention consists in fixing to the back of each drawer hinged flaps, which open as the drawer is pulled out. For ordinary drawers three flaps are used: two (one at each side) which when open fall downward and keep the drawer laterally true; and a centre flap which opens out like an ordinary door, this flap keeping the drawer horizontally true.

Fig. 1 shows an elevation of the back of a drawer fitted with such flaps closed. The thickness of the flaps may be $\frac{1}{2}$ in., or less; a drawer with $\frac{1}{2}$ in. flaps would be only less by this thickness than the width of the cabinet.

Fig. 2 is a sketch of the flaps when open. The flaps, being prevented by checks from opening to more than an angle of about

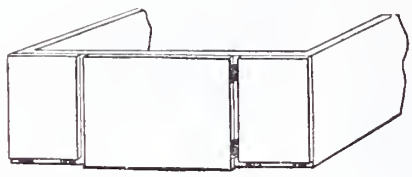

Fig. 1.

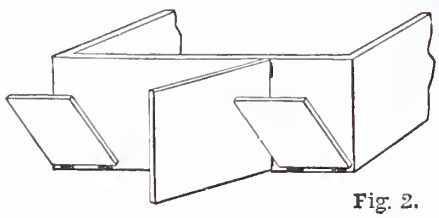

Fig. 2.

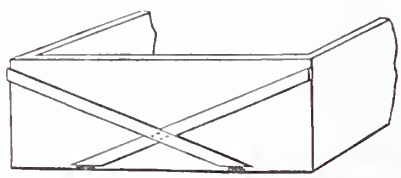

Fig. 3.

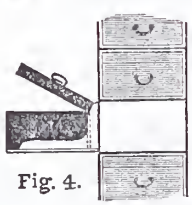

Fig. 4.

Fig. 1.—Back of Drawer fitted with Flaps closed. Fig. 2.—Back of Drawer fitted with Flaps open. Fig. 3.—Substitute for Central Flap. Fig. 4.—Sliding Shelf fitted with Flaps.

45 degrees, will close of themselves as soon as they press against the back of the cabinet, should they not be closed before reaching the back when the drawer is being pushed in. It is suggested that a slight spring be fixed to each flap, to force it outward, though it will be found that even without a spring the flaps, by friction against the sides, do in practice usually open of themselves.

Drawers fitted with such flaps *cannot*, however far they may be out, stick when being pushed in, because the flaps which act as guides touch the sides, and these flaps, when the drawers are being pushed in, coming in contact with the sides, commence closing, and so give the drawer a start to slide easily. The expense of providing such flaps is trifling, as they can be made of deal wood.

The vertical flap, which keeps the drawer from *dropping*, is necessary if it be intended to pull out the drawer more than half way; but where it is not considered necessary to pull it out more than half way, then the vertical flap (the centre one) may be dispensed with, and one flap extending across the back of the drawer, fitting the sides, is all that is necessary. This flap may be simply made with two pieces of wood crossed, as in Fig. 3, which shows this description of flap closed.

The inventor considers, though, that the chief advantages to be derived from the invention (for which object the flap which opens vertically is also used) are, that drawers may, when so fitted, be drawn *fully* out, and may be pushed in again with the greatest ease. No care as to the manner of drawing out or pushing in need be observed, as the drawers will be found to move freely however one-sided or carelessly the necessary force is applied.

It is obvious that drawers which can easily be drawn *fully* out and pushed in again must possess advantages over those which do not permit of this. Drawers, as at present constructed, cannot be pulled fully out, and consequently their whole capacity is often not utilised.

Drawers of small width are at present the most liable ones to stick when being pushed in, and so their utility is impaired. This invention entirely removes the difficulty, and the inventor is of opinion that drawers of small width will now become more used. The invention should be especially applicable to drawers containing heavy weights, such as coin, etc. Sliding shelves may also be fitted with this invention, and shelves so fitted would be especially useful for the reception of deed and other boxes, as the drawers could be pulled out and the boxes opened whilst they were still upon the shelf, as in Fig. 4.

This is the only invention which permits of the drawer or shelf being *fully* drawn out without any supports in front.

## PRACTICAL PAPERS FOR SMITHS.

BY J. H.

FORMATION OF RINGS—PUCKERING OF METAL DUE TO BENDING—BENDING BLOCKS—BLOCK FOR BENDING FLAT BARS—BLOCK FITTED WITH SCREW FOR GENERAL WORK—DETAILS OF RING FORMATION—WELDING ENDS—APPLIANCE FOR LIFTING HEAVY RINGS—USEFUL BLOCK FOR MAKING RINGS IN QUANTITY.

IN previous papers in Vols. I. and II. of WORK I have taken a general survey of the various typical operations performed by the smith. The historical and ornamental branches of smiths' work formed the first section; the general practice of modern forging by drawing down, upsetting, welding, and shaping by various tools, with some practical examples, formed the second. In this, the third series, I shall discuss certain of the special operations and branches of this craft, which, though not of necessity distinct from its general practice, can nevertheless be better treated under separate headings. In this way I hope to write on the methods of making holes, on the working of steel, the making of tools, hardening and tempering, model work, repairs, and some other matters of a special character. The present paper will deal with the formation of rings.

Curves and rings of light section are easily bent over the beak of the anvil or around a mandrel of suitable diameter. The case is different when the sections are heavy, and then some kind of appliance is necessary. I shall therefore describe some serviceable bending blocks.

It is easy enough to bend iron flatwise, but not so easy to bend it edgewise. The reason

apparent if we consider that when a wide ar is bent two things must happen. Along ıe centre of the bar (Fig. 1, A A) there will e a portion of metal that is simply bent, ithout compression or extension of fibre. ut on the outside, B B, of this neutral axis ıere are successive zones of metal that re variously extended, and on the inside, C, of this axis there are zones of metal ıat are variously compressed. We know hat must happen then. The metal in ension and the metal in compression will eek relief from the intense stresses to hich it is subjected by corrugation into lanes above and below that of the main ody itself. It will become wrinkled and uckered upwards and downwards. This endency has to be corrected by hammering, r by the use of mechanical devices.

Quite an infinity of devices are resorted o in the smith's shop for the purpose of ending work of various sections and outnes. The making of a cast-iron templet r bending block is a question of relative ost. In some cases, where only a few plain ieces have to be bent, it will not pay to ake the simplest block. In others, where here are dozens, scores, sometimes hundreds f pieces, all alike, it pays to cast the most laborate blocks, and fit them up with lips and cottars, or whatever besides may e necessary. Of course, I cannot show a ithe of the blocks that may be formed. When a smith sees what is wanted in forgngs, it is usually easy to design blocks for hose forgings.

Fig. 2 shows a very common type of block ısed for bending flat bars. Made in suitble sections, it is also often employed for ending T-iron. As drawn, the working dge, A, is a regular curve; but other urves could be imparted to it equally well. The block has a stout cottared pin cast in it, rojecting from its bottom face. This pin asses through a suitable hole in the levelng block, C, and is cottared beneath. This s, on the whole, the most convenient nethod of holding cast-iron templet blocks lown—better than having movable clips. ), D are clips, by which one end of the bar, E, to be bent is confined in its groove. They ıre fastened with bolts through some of he holes which are usually cast in profusion n all bending blocks, and the cottar, F, passng through slot holes in D, D, holds the ar, E, fast down in its groove. As the free nd of the bar, E, is carried farther round, nore clips are brought to bear upon it; otherwise, the bar would rise up from its eating.

Fig. 3 shows a common levelling and bending block, fitted with a screw for general work. Such a block is useful for several purposes. Upon it, bars and plates of metal that have to be made true can be straightened and levelled by hammering. From its face, many forgings in process of formation can be tested by the square, one edge of the square being laid upon the block, and one edge against the vertical face of the work. The bevel can be similarly used. Work can also be taken out of winding upon its surface; and it is used largely for bending iron bars to various curves. The block, A, is pierced with numerous holes of circular, and of slot, shapes, for the purpose of receiving pins of various kinds, which form the necessary points of leverage when bending. There should be no stint of holes, short of unduly weakening the plate. At B there is a screwed block, secured to the plate with a shank or pin through which a cottar way passes. The driving-in of the cottar underneath secures this block in position, and by the interposition or removal of a ring the height of the block can be varied. Through the block the powerful square-threaded screw, C, passes, and is operated by the heavy cross, D. It is evident that if pins be inserted in holes, say, at *a*, *a* or at *b*, *b*, they will afford points of resistance to a bar that is laid against them when pressure is brought to bear about its central portions by the screw, C. As the ends of the bar cannot yield, the result is that it will become bent. By shifting the positions of the pins into other holes, the curvature of the bar can be varied at pleasure.

Fig. 4 illustrates another method of the making of a ring upon the bending block shown in the previous figure. A is the block itself; B is a sweeped templet casting, cottared down to the levelling block through the medium of rough holes cast in the sweeped templet, the pins passing through any of the holes cast in the bending block that happen to be conveniently situated. The block is set so that its curvature is made to follow round some particular hole in the bending block, in order that the radius bar or lever, C, with its roller, D, may operate with equal pressure upon the ring E in every position. The lever moves upon a substantial pivot, F, whose shank or pin passes through the plate, and is cottared below. The detail of this fitting is shown in Fig. 5, where F is the solid body of the shank, whose pin, G, passes through the bending block, A. H is the pin upon which the bar, C, pivots, and J is a collar, one or more in number, for adjustment for height. K, K are top and bottom cottars.

One end of the bar, E, to be bent (Fig. 4), being heated, is first secured at one end of the curved templet. As these templets are of necessity of quite a special character, made to suit each special job, and not for general work, it is usually praeticable to cast a stop at the end where the bar is first secured. Such a stop is shown in Fig. 4, at L, and in detail at Fig. 6.

This particular templet represents one used for making rings from which to cut the reversing links of the motion work of engines, the links being of the type shown in Fig. 7. Where such links are made in quantity, this is by far and away a cheaper method than forging and filing, or machining each link separately. Making a ring with radius equal to the curvature of the link, it is turned all over in the lathe, and then the separate links are slotted out of this ring—a dozen or fifteen, as the case may be, and all are exactly alike.

In such a case as this, a flat oblong stop, L, cast on one end of the templet block, is suitable. We know that when bending any rigid article it is very difficult to get the extreme ends properly curved—they stick out at a slight tangent. Now, in this case, the stop will hold the end perfectly fast, and the curvature can be commenced from the very end.

To prevent that end from rising during the process of bending, the clip, M (shown in detail at Fig. 6), is made to bear upon it. This is a piece of wrought iron of stout section, pierced with a hole for the cottared pin, N, screwed into the bending templet. The long leg of the clip rests upon the face of the bending block; the short leg is pressed down upon the bar to be bent by the pressure of the cottar. The bar is thus pinched at one end.

The opposite end, if heavy, is supported by one of those kinds of appliances common in smithies (see Vol. II., p. 805, Figs. 114, 115). A man, or two or three men if need be, stand at that end, and pull the bar by main force round the curved templet, the supporting rest being moved along with the bar. The bar has a tendency to crumple up along the portion where the bending is taking place. This is corrected by hammer blows from a sledge. Also to prevent the bar from becoming curved to unequal curvatures, pins are inserted at intervals in holes cast in the plate, and iron wedges, o (Fig. 4), are driven between these pins and the bar.

Much force is required to pull round the roller, D, against the edge of the iron. To avoid having a long lever sticking out in the way, a bar, P, is often slipped over the end of the radius bar, C, and removed when not in actual use. The mechanism of the roller, D, is shown in detail in Fig. 5. A block, Q, slides along the bar, C, and may be wedged at any radius with the wedge, R. A stout bolt, S, is tapped into or forged on this block, and the roller, D, slips over it, and is held up by the nut underneath.

In an ordinary forge fire a heat cannot be taken over a great length. Therefore, after a short section of a bar is bent, say, from twelve to fifteen inches, it has to be released from the templet and put back into the fire to get the next section hot; and so on, and so on, until the entire ring is complete. Each time it is put back on the block the portion already curved is secured with wedges. Sometimes also one or two clips like M (Fig. 6) are cottared down over the bar to prevent it from rising up. When the curvature is completed and the circle formed, the ends have to be welded.

The ends of the ring are upset before being brought into juxtaposition, as is usual in making weld joints. They are spread out in all directions—top, and bottom, and edges. But these upset edges are not welded to each other, but are united by means of intermediate "stick in" pieces, thus:—Into the V-like space on one side formed by the abutting ends, a square bar of iron (Fig. 8, A) is laid, and all being simultaneously brought to the welding heat, a few blows of the hammer serve to produce union of the bar and the ends of the ring. The bar is not cut off to the neat length required at first, but any length of bar that happens to be handy is taken, and the end only is brought to a welding heat, the opposite cold end serving as a porter. After the welding is done, the supplementary end is cut off with the hot set.

The ring is then turned over, and a similar "stick-in" piece, B, welded into the opposite V, precisely in the same fashion as in the first case. Of course, the surfaces and edges are very rough and uneven; but the essential work is accomplished, and the rest is merely a matter of battering off the faces with the flatter, and the trimming of the edges with the hot set and flatter.

A heavy ring such as this cannot be manipulated by hand until the men's hands are relieved of its dead weight. Fig. 9 shows a simple and effective rig-up for this purpose. Use is made of the movable jib, which in some form or another is a belonging of most forges. The jib is pivoted against the wall. Upon its cheeks, A, A, runs the jenny, B, consisting of four wheels and carriage, with depending hook, C.

To this hook is attached a lever having a long arm, D, and a short arm, E. At the end of the short arm there is a square nut, F, screwed to take a coarse, square-threaded screw, G, which passes up clear by the side

of the crane. At the lower end of this screw there is a swivel, H, through which the screw works, being turned by a podger passing through the hole in the boss at the lower end of the screw, G. From the lower end of the ring, being rapid and immediate in action. The exercise of very little force, such as a man can apply with one hand, is sufficient to raise and lower the ring upon the anvil or the bending block. It can then

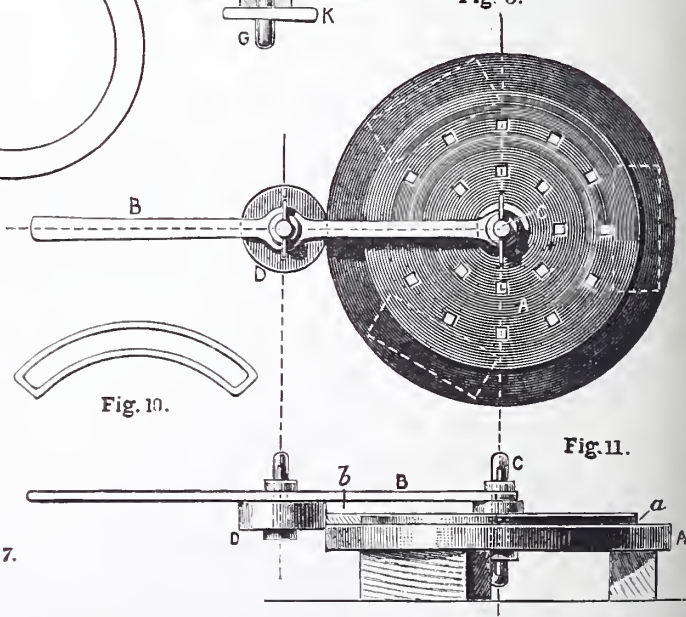

**Fig. 1.—Diagram to illustrate Tension and Compression. Fig. 2.—Bending Block. Fig. 3.—Levelling Block, with Screw. Fig. 4.—Ditto, with Bending Templet. Fig. 5.—Details of Lever. Fig. 6.—Details of Clip. Fig. 7.—Reversing Link. Fig. 8.—Welding the Ring. Fig. 9.—Apparatus for lifting Heavy Forgings. Fig. 10.—Iron Segment for increasing Radial Capacity of Templet. Fig. 11.—Circular Bending Block.**

swivel depends the chain and clip in which the ring is suspended. Now, adjustment can be made of the height of the ring, first by turning the screw, G, the range of height being equal to the length of the screw ; and second, by pulling at the chain, J, at the long end of the lever. The latter is the adjustment used during the manipulation of be turned about, or turned over, or moved in any position that may happen to be required.

If a ring, or segment of a ring, is wanted larger by a few inches only than the ring, B (Fig. 4), for which the templet is primarily made, the smith will, to save the expense of a new block, make a filling-up-piece (Fig. 10) of square bar of the width required to make up the difference in diameters.

Fig. 11 shows a block of a useful type for employment when a large number of complete rings of the same size are required. The principle of its construction is very similar to that rigged up on the levelling block (Fig. 4) ; but in this case a complete circular disc, A, instead of a segment only, is used. A lever, B, is pivoted in the centre of this disc by means of a cottar and pin, C, or a bolt. A roller, D, is pivoted on this lever. The ring is bent round the

nnular recess, *a*, in the disc, and the roller, eing pulled round with the lever, is pressed gainst the edge of the ring, which, confined etween the roller, D, and the edge of a ecess on the disc, as shown by shading at *b*, annot fail to become circular.

The ring will have to be held down at arious sections with clips, as in the previous xample, for which purpose the holes cast bout the central part of the disc are tilised.

A templet like this can also be used for ings slightly larger in diameter and of dif- erent widths, by placing rings around the entral portion, *a*, of the recess, and by alter- ng the diameter of the roller, D. It is, of ourse, not necessary that the periphery of he roller should coincide with the periphery f the disc. If the ring to be turned is arger than the outside of the disc, then the oller will be correspondingly smaller. If he ring is smaller than the disc, then the ottom of the roller will touch on the bottom f the recessed portion.

When a smith wants bending blocks of his kind, it is as well to know that complete wooden patterns are seldom made for them. If a pattern segment of the block is given to he moulder, with a sketch or drawing of he complete block, with suitable instruc- ions, that is all that is required. The noulder will place also ny number of plain ores in the mould for he pin-holes with suffi- ient approximation to he accuracy wanted in work of this class.

## A DRYING-HORSE FOR BOOTS.

BY HIRAM PRICE.

Standard for Boot-Horse —Iron Rack for Boots — Fastening Rack — Alternative Rack in Wood.

Being some time since, in muddy weather, at a house where all domes- tic matters were ad- mirably managed, I ob- served that each even- ing at bed-time a board, on which were ranged the boots and shoes of the family—a numerous one—was placed before the fire-place. The board served as a tray; all the boots were brought in upon it bodily, and could in the morning be carried upon it altogether to the place where boots were wont to be blacked. The idea struck me as a good one, yet the arrangement had certain defects—the boots were not raised to a level with the grate, and did not, there- fore, derive all the benefit they might have done from the drying fire, and as they rested on their soles, those parts which needed it most had the least chance of drying. I put on my considering cap, and debated with myself how I might best improve upon the plan for the advantage of my own house- hold.

The result was the contrivance shown in the three first of the annexed diagrams, which I find to work satisfactorily.

The end elevation (Fig. 1) is one of the two standards of my boot-horse. I cut it from stout board, the upright piece being, of course, mortised into the foot. It is of such a height as to bring the boot well up to the level of the grate. I made the standard of my own horse 2 ft. high—which, I imagine, would be a fair average height—but some grates might still need it to be a little bit higher, some a little lower. In this diagram, A and B are the ends of two wooden bars (indicated by the same letters in the front elevation, Fig. 2), which act as braces to hold the horse together; the

**Fig. 1.—Boot-Horse (End Elevation). Fig. 2.—Front Elevation. Fig. 3.—Plan of Rack. Fig. 4.—Alternative Wooden Rack. Fig. 5.—Plan of Boot-Rack as made in the old-fashioned Boot-Horse.**

Fig. 3

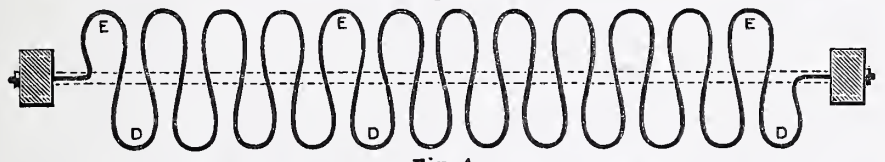

Fig. 4.

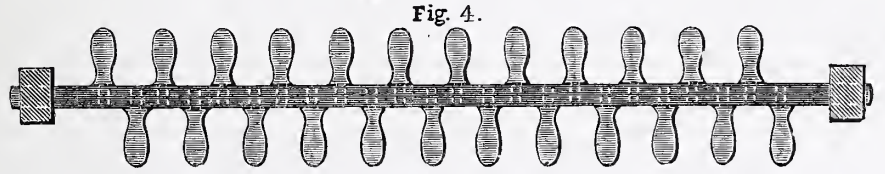


upper rail, A, is, moreover, the handle by which the contrivance is lifted.

Fig. 3 gives a plan of the iron rack to hold the boots. All other parts I made myself, but for this I called in the aid of a blacksmith. It is made of a thin (⅜ in.) rod of iron, bent into the waved form sketched in the figure; and as, when thus bent, it would of necessity give way under its load of leather, it is supported by the stouter iron rod, indicated in the plan by dotted lines as running beneath its centre. To this at its ends it is welded. This stouter rod passes through the uprights, and is secured by nuts, as shown at C, Fig. 1. In Fig. 2 the rack, seen edgewise, is marked C.

Supposing that the side of the horse on which are the points, D, D, D (Fig. 3), is that set nearest to the grate, all the boots hung upon it would have their soles brought opposite to the fire, and be in the most favourable position for drying; whilst those on the side E would have their upper leathers nearest the grate, and at a more respectful distance, which, indeed, would be better for the boots. In some cases only the soles may need much drying, and these may be hung on the side E; if all need drying equally, the whole horseful may be turned in a moment.

The horse before us is 4 ft. 6 in. in length —longer, indeed, than most families would need, as it is capable of drying a dozen pairs of boots at a time. But by making it of this length, I wished to show how easily the comfort of the largest family might be provided for in this particular. In most houses a shorter horse would suffice—my own is 3 ft. long. A horse of a greater length than that given would be cumber- some; and should my plan be adopted—as it might be with advantage—in schools or hotels, I would recommend that instead of a longer horse, *three* horses of moderate lengths should be provided, which, being arranged so as to form a sort of fender round the fire-place, all warmth would be utilised.

The iron rack is, in my opinion, strongest and best for the purpose, and well worth its trifling extra cost; but as it is to home- workers, like myself, that this contrivance will more particularly recommend itself, and as many home-workers like to carry through any work they under- take from beginning to end with their own hands, I give an alter- native rack in wood, which will be an effi- cient substitute. This is shown in plan in Fig. 4. It consists of a centre-bar, made of 1 in. or ¾ in. board, 3 in. deep, along the middle of which, at intervals of about 2 in. from centre to centre, are bored a series of ½ in. holes; into which, on each side alternately, pegs are glued — the pegs being sawn from ¾ in. or ½ in. board.

The scale on which the diagrams to this Drying-Horse for Boots are drawn is 1 in. to the foot.

[Of a truth, there is nothing new under the sun. When I was a boy, far away back in the thirties of the century, when the glorious memories of Waterloo were far fresher than they are now, being revived from year to year by the annual recurrence of the Waterloo Banquet, and when Wel- lington boots and Bluchers were generally worn, I remember, among the equipments of my father's bedroom, a boot-horse of solid mahogany, very much like the drying- horse described by Mr. Price. It differed from the latter in being as high as a towel- horse. The standards were connected by three rails—one at the top, one in the middle, and one at the bottom. In the top rail were inserted on each side turned mahogany pegs, on which shoes and slippers were hung; and on the upper surface of the central rail was placed a shelf, notched,

as shown in Fig. 5, to take Wellington boots and top-boots, the boots being inserted in the notches, soles upwards, just below (according to this position) the stiffened part of the heel. Furniture was furniture in those days: as witness the fine old carved four-post bedsteads. I have never met with more than two of these old-fashioned boot-horses; but, doubtless, some are to be found, even at the present time, in good old country houses.—ED.]

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 48.—THE "ART DECORATOR."

IF I remember rightly—and it is scarcely worth while to refer to back numbers, or even the Index to Vols. I. and II. of WORK, to see whether memory is right or wrong, when time presses, and much has to be done under its pressure—the *Art Decorator* has been already mentioned in these pages. Nevertheless, its publishers, The Electrotype Company, 80, Fleet Street, London, E.C., have sent me some specimen pages (forming together Part 19 for July, 1891), and these pages, or sheets of drawings, which are sent out in a wrapper, are, generally speaking, so cheap and so good—the Parts being sold at 1s. each—that it is well worth while, in the interest of the readers of WORK, to call attention to it again. The illustrations, or rather the sheets, are five in number, and if the title page and contents of Vol. II., which is included in the Part, be taken to rank as equal to one of them, the average price of each sheet is 2d. The first sheet, in black, gold, and white on a grey tint, is devoted to emblems of great artists, including Dürer, Holbein, Michael Angelo, Raphael, and Rubens; and, as the characteristic portraits of each are given, the sheet itself is well worth the price charged for the whole Part to decorators who introduce portraits and the human form into their work, as suggested by my valued contributor, "A London Decorator," in his design for a ceiling in stencil for a sitting-room, in Vol. II., page 133. Then follows a sheet of examples for wood inlay, a centre panel and borders, the former being quaint in its introduction of a rabbit and fowls among the foliage, and the whole characterised by elaborateness of design involving the utmost care in the execution. The woods, too, are well set forth in black and white and various tints of brown. The third, a lunette, "The Vine," with two nude figures of children, a boy and a girl, by Professor G. Sturm, is a photo-print by E. Schreiber, of Stuttgart, suggestive of a sketch delicately executed in Indian ink, and this, perhaps, is the gem of the whole Part. Two chromo-lithographs complete the tale of plates—one of three polychrome friezes in Italian renaissance, and the other of two decorative landscapes, rich in colour, suggestive of the Bay of Naples, but with skies savouring far more strongly of our British climate than the cloudless unbroken blue of sunny Italy. To all decorators and amateurs I strongly recommend the *Art Decorator*. A new volume is commenced with Part 19; and I must tell my readers that if the successive Parts are not secured as they appear, the back parts, after a time, like the Sibylline books, are subject to an increase in price. And this is a good and valid reason for not putting off till next year a purchase which you can make now on far more advantageous terms.

### 49.—BANNING'S PATENT BOTTLE BRUSH.

Mr. R. Banning, Mineral Water Manufacturer, 56, Legge Street, Birmingham, has sent me a photograph of his new Patent Bottle Brush, for the inside and outside cleansing of bottles. The bottle brush itself is so constructed that it may be worked, and, from its appearance, I should say, must be worked, in a lathe. Three brushes, consisting of knots of bristles set in twisted wire, are set at one end in a circular piece of lignum vitæ with brass fittings, and at the other end in a circular plate. Another wire proceeds centrally from the lignum vitæ boss, and through the centre of the plate, terminating in a small brush not unlike a shaving brush. The three outside brushes are set at equal distances from one another. Mr. Banning kindly offered to send me one that I might make trial of it; but washing bottles in a lathe is not exactly in my line, and I have no lathe that I should like to put on such watery duty. He has made trial of his invention now for about six months, and as he says his object is to sell his patent rights, I have now done as much as I well can in giving his address and mentioning the existence of the brush. It seems to me that it is likely to be useful in any place in which the washing of bottles is carried on on a large scale; and as ale and wine bottles can be washed with it, it is to be presumed that it is a good bottle washer all round.

### 50.—BIGGS'S PATENT TUBULAR REVERSIBLE LOCKS.

Some time ago, a gentleman living in the neighbourhood of Northampton called my attention to Biggs's Patent Tubular Reversible Locks, which are sold by Messrs. A. M. Perry & Co., of that town. I wrote to Messrs. Perry & Co., asking for samples, and they forwarded my letter to the Tubular Lock Syndicate, Limited, from whom I received a reply enclosing drawings and press notices, but no samples, so that I am unable to say anything respecting the locks themselves beyond what I can gather from the papers mentioned. Moreover, I was bidden to note this:—"Of course, if you put a notice in your paper it must be free of charge." This was unnecessary, as no charge for notices of articles in WORK has ever been made, or will ever be made, but it seems to intimate that it is not every paper that is as blameless in this respect as WORK. This, however, the Tubular Lock Syndicate, Leadenhall Buildings, London, E.C., did not know, and so made a slight mistake through want of better knowledge of WORK and its aims and purposes. I may add that, as many of my readers very well know, samples sent for inspection are always returned if a request is made to that effect. Although I cannot speak of these locks by experience, I know the Yale Lock, which seems to be made on similar lines, and I can testify to the goodness and utility of that. All tubular locks are easily fitted and fixed, and they are particularly well adapted for the purposes of amateurs in every way. Therefore, I trust that such of my readers who want locks for new doors and new drawers will do as I intend to do when I am wanting this kind of thing—namely, give Biggs's Patent Tubular Reversible Lock a trial, and if they like it mention it to their friends. Handles of doors, too, for the most part are troublesome things, but the Syndicate supply a great variety of mortise lock furniture in fancy woods and brass, to be used with the tubular locks, and which appear to be unique in the manner of fixing, and likely to be far more durable than the door handles in ordinary use. These door handles are made on Pitts's Patent.

---

*** I have to acknowledge the regular receipt of *The Machinery Market and Exporter*, published at 181, Queen Victoria Street, London, E.C., and *The Amateur*, published by Mr. Henry Zilles, 24 & 26, Wilson Street, Finsbury, London, E.C. These serial publications are well worthy the attention of all readers who take an interest in machinery and all kinds of wood-working of an ornamental character.

THE EDITOR.

## NOTES FOR WORKERS AND HINTS TO INVENTORS.

HOT-AIR ENGINES.—Amateurs of an inventive, as well as constructive, turn of mind may usefully direct their attention to a much-wanted article—a really light and *cheap* hot-air engine sufficiently powerful to drive sewing-machines, fans, etc. Those at present in the market are all too clumsy and heavy. Robinson's, recently described and illustrated in several technical journals, most nearly approaches the ideal pattern, but is open to much improvement in the direction indicated.

PIANO HAMMERS.—Nearly all the hammers made for English pianos have a tendency to harden on the striking face after a few years' use. The felt buffing becomes partly compressed and partly worn away, the result being that the strings emit an unpleasant "tin-kettle-like" sound. As re-buffing the hammers in many parts of the Colonies and India is impracticable, except at a heavy cost for transporting the instrument to one of the large towns where repairers can be found, some device to either easily replace the old buffing with new or, perhaps better, change the entire hammer head would find much favour.

A VERY NOVEL ADVERTISING MACHINE.—Inventors are frequently asked if they cannot devise some entirely novel method of advertising. Originality in such a direction, however, seems somewhat difficult, if, as is usually stipulated, cheapness and efficiency have to go hand in hand. It has been reserved for an American genius to suggest a device, the home manufacture of which is within reach of the humblest purse, while dispensing with the services of the bill-poster, or the space of a show-window or hoarding. It consists in an "advertising arrow," projected from a toy gun of somewhat greater strength than that usually sold to children, and intended to be fired at trees, fences, wooden buildings, etc. etc., which the sharp point of the arrow will readily penetrate. It certainly has the defect of being useless against stone or brick buildings, but there is wood enough still employed throughout all civilised countries to give the new idea a pretty wide field of operation.

The arrow is feathered with light cardboard in four sections, upon which the advertisement desired may be printed, while the heel is bound round with cord to keep the cardboard in place. The gun, of which elastics form the springs, has a longitudinal kerf slit along its entire length to allow one of the card "feathers" to travel in it. If preferred, the advertisement printed on a tag may be attached separately to the arrow. To people in want of a new method of advertising, this device will commend itself, especially in country districts.

"CASTOGRAPHY."—Our French contemporary, *La Nature*, describes an ingenious method of producing ornamental designs on cardboard, to which the inventor, Mr. Mills, an American, has given this title. It must, however, be premised that only people possessed of some artistic talent could essay the process, which consists in going over the outlines of a drawing or written device upon the card with a very sharp penknife, held so as to form a more or less acute angle with the surface. With the back of the knife, the portion cut is raised so as to be converted into a sort of bas-relief, and this, on being illuminated sideways, presents lights, half-lights, and shadows, such as would result from a carving in stone. It is not easy to secure the necessary effect on a first trial—the tendency of the knife, which must be very sharp pointed, being to slip through the cardboard. This, however, is soon overcome by practice, though few are likely to acquire the lightning rapidity of Mr. Mills, who produces most beautiful effects in less than a minute, dispensing with any previous outline. Some approach to the idea has already been made by the stamped lamp-shades on sale at many well-known establishments, but they do not compete with the artistic results achieved by the ingenious American. Readers, anxious to find a new way of passing spare time, might do worse than turn their attention to this interesting occupation.

## SHOP:

CORNER FOR THOSE WHO WANT TO TALK IT.

** In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*, answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**Speed of Waggon.** — INCLINED PLANE. — The riction of the usual railway waggon properly ade, with its bearings well lubricated, is about lbs. per ton on a horizontal line. This corresponds ) an inclination of one in 280, so your waggon ould start and run on rails with the inclination ou give: viz., one in 108. The accelerating force n the waggon will be to that of gravity acting irectly in proportion to the rate of inclination; us, if $v$ = velocity per second in feet acquired fter the force has acted for one second, then $= \frac{32{\cdot}2}{108} = 0{\cdot}298$ ft. per second if there is no friction; ut the friction represents an incline of one in 280, nd, therefore, all there is left to cause motion is a ise of $1 - \frac{108}{280}$ in 108: that is, a rise of $1 - 0{\cdot}385 = 0{\cdot}615$ n 108, or 1 in 175·56. This gives for the acceelerating orce parallel to the rails $\frac{32{\cdot}2}{175{\cdot}56} = 0{\cdot}183$. Replacing or 32·2 by this in the ordinary formulæ for falling odies, your questions are solved as follows:—If = the distance (corresponding to hcight in falling odies)

$$v = \sqrt{2\,g\,d} = \sqrt{2 \times 0{\cdot}183 \times 99} = 6{\cdot}019 \text{ ft.}$$

er second at the end of the run, giving an average elocity of $\frac{0 \times 6{\cdot}019}{2} = 3{\cdot}0095$ ft. per second. If = time in seconds to make the run, then—

$$t = \frac{2\,d}{v} = \frac{2 \times 99}{6{\cdot}0195} = 32{\cdot}89 \text{ seconds.}$$

ou may not find this realised in practice, for two easons. First, the data I have taken for friction ay not apply to your waggon; second, no allownce for resistance of the air has been made, but as he speed is so low this would hardly be perceptible. ou can, of course, apply this method with other ata.—F. C.

**Cracked and Dull Polish.**—TABLE TOP.—The op of your table has, undoubtedly, been hurriedly inished. The cracked, dull surface to which you efer is known in French polishers' parlance as "sweating." It may be due to the fact that the workman was insufficiently paid for his labour, so ould not afford to spend the necessary time on it to urn out work that will "stand"—*i.e.*, retain for an ndefinite time its original lustre; or it may be that oo much oil has been used. The fact that only the able portion is cracked and dull would serve to how this, this portion having been finished out vith the rubber. The turned portion being mostly arnished out, consequently less oil is used there. t would, of course, be better for you could you mploy a French polisher's services for a few ours. He would probably soon restore it by working t up again with a little polish and spirits. If you lo not, as you say, care to employ one, the next est thing to do would be to wash it with a little veak soda and water—common washing soda, the ize of a walnut, dissolved in a pint of warm water; vipe dry, then use a little of the reviver made as ollows: ½ pint lime water, ½ pint linseed oil, horoughly well mixed; then add ⅛ pint of sweet oil, nd well mix; then thin down with nearly ½ pint of urps. Apply with soft rag or wadding; wipe off vith soft clean rag fairly moistened with methylated spirits.—LIFEBOAT.

**Polishing Tool Handles.**—TURNER.—A sufficient polish for these is sometimes obtained by holding against them, whilst revolving in the athe, a handful of fine turnings of the same kind of vood as the handles, especially if wiped over first vith a little linseed oil. Many turners use the ollowing:—Dissolve 1 oz. of sandarach in half a pint of spirits; shave 1 oz. of best beeswax in sufficient urps to form a paste. Mix the two together by legrees. Apply with a woollen cloth whilst the work is in motion; polish with soft clean rag. Thus reated, they should appear as if highly varnished; whilst others apply a little French polish with wool or flannel, finishing off with a few drops of methylated spirits on a piece of soft chamois leather; others, again, simply press a piece of beeswax against them while revolving. Experiment with hese till you find the one to suit your purpose best.—LIFEBOAT.

**Polish Reviver.**—PIANO.—I have myself long discarded the reviver you mention on account of its disagreeable smell, caused by the vinegar soon turning sour, and have used with satisfactory results one made as follows:—¼ pint lime water, ¼ pint linseed oil, thoroughly well mixed; then add ⅛ pint sweet oil, well mixed; then thin down with nearly ½ pint of turpentine. Apply with wadding or soft rag, wipe off, and finish with soft clean rag fairly moistened (not wet) with methylated spirits. Of course, if the work is very dirty or sticky with wax, it should be well washed with weak soda and water to be effective. I find this reviver and the mode of using it the best, for, apart from the doing away with the disagreeable smell, and dispensing with the use of wax—which, by-the-bye, has little to recommend it as of use in reviver, except as a dust accumulator—I find that if the reviver does not bring up the work so satisfactory as desired, it is easy to take a rubber of "half and half" and work it out, thus bringing up the polish to its original lustre: a thing next to impossible if using many of the so-called revivers. —LIFEBOAT.

**Tinning Copper Pans.**—J. F. (*Elgin*).—You wish to know how to re-tin copper stewpans that have been tinned inside and out. These articles are more correctly termed bain-marie pans, or bain-marie pots, as some call them. They are some trouble to re-tin unless you have the use of a large bath of tin, in which case there is no difficulty in the matter, as after the usual pickling, scouring, etc., with which I presume you are acquainted, they are placed in the bath, and tinned by rubbing with the tinning rod, with an occasional dip all over to keep them hot, and, when well tinned and thoroughly hot, lifted out and rapidly wiped. I have, however, had to do them when limited to half an ingot of tin—about 14 lbs. In this ease I make a square pan of stout sheet iron, dog-earing the corners to prevent the molten tin from running out. This pan must be large enough to allow the largest pan to lay in on its side, handle as well; place a pan in the tin (when melted over the fire), and flow or splash, as it were, the tin on to the pan. Keep turning it over, so as to get it equally hot all over. To do the inside of the bottom, it will have to be stood upright in the pan, and well rubbed with the tinning rod, using plenty of finely-pounded sal-ammoniac. When completely tinned, wipe as usual. Some tin them all first, and then remove the pan, and make each one hot again over a clear charcoal fire, and wipe. You will perhaps find this the easiest way. A little dust of sal-ammoniac thrown on as you begin to wipe will help a great deal. To wipe the insides, especially of very small ones, a piece of stick with tow tied round it will be found useful. With regard to the measuring for price, they are measured from lag to brim—that is, diagonally from one side of the bottom to the other side of the top—but half as much again is allowed for the extra tinning; for instance, a bain-marie pan measuring 8 in. would, if paid for tinning at 1d. per inch, which is a fair price (for the tinning only, not to the customer), be reckoned as 1s.; a 6 in. pan would be 9d., and so on; covers the same. One caution, in conclusion: do not get the tin too hot so as to burn it; it is no joke to spoil 14 lbs. or more of block-tin.—R. A.

**Size from Parchment Scraps.**—WORKONIAN. —We doubt whether size could be bought positively made from the above. To make it, the scraps of parchment should be put in a bag (flannel by preference), which must be hung in a vessel of water and boiled till the parchment is boiled down. By removing some of the water, and ascertaining if, when cool, it sets to a clear jelly, it will be seen whether the boiling is sufficient; when it is, squeeze the bag (but not too hard) to force out the remaining gelatine. Evaporation by boiling will make the size stronger if required.—S. W.

**Sale of Poisons.**—RAYNOR.—By the Pharmacy Act of 1868, which please consult, it is enacted that none of the poisons there enumerated shall be sold by any person unless he be registered as a chemist and druggist. This applies to poisons whether sold alone or in combination. RAYNOR should get the above Act, with any additions that have since been made (which he can do through any bookseller), and see whether the poison in which he is interested is one of those mentioned, or whether it comes within the meaning of the Act.—C. C. C.

**Lead Burning.** — A PLUMBER, H. W., AND OTHERS.—A lead-burning machine is a self-acting, self-regulating gas generator for giving a continuous current of hydrogen gas. It is a cylindrical vessel, about 3 ft. high and 12 in. in diameter, divided into three compartments, having communication with each other by means of pipes and stop-cocks. Zinc cuttings are placed in the bottom one, and dilute sulphuric acid in the top, and the gas generated by these two substances when in contact with each other flows into the second chamber, and thence to the blowpipe, where it combines with air under pressure. I cannot give you a sectional drawing, as I have never had one to pieces; but I must say that I do not think it would be practicable for you to make one yourself with the sole aid of a drawing and description. There is a patent lead-burning machine and blower manufactured by Mr. P. J. Davies, 78, Earl's Court Road, Kensington, that I have heard highly spoken of, and as you reside in London it would be worth your while to call and see it. Mr. Davies is a well-known plumber, and author of a standard work on plumbing, and would, no doubt, be pleased to show you the machine and its working.—R. A.

**Answers in "Shop."**—B. A. W. (*Croydon*).—Replies in "Shop" must take some little time before they can appear—for these reasons: There is a great demand upon "Shop"; four pages of the paper have long been devoted to "Shop," and this is rather a large proportion of the journal itself; and all replies are submitted to outside specialists, who are paid to give careful and adequate replies. There is the "good all-round man and London Directory" principle of dealing with correspondence, but this is not adopted in WORK.

**Chemistry of Photography.**—W. T. (*Stratford-on-Avon*).—The best publication you can study is "Hardwick's Photographic Chemistry."—D.

**Watch Oil.**—W. J. (*No Address*).—Grimshaw & Baxter, 33 and 35, Goswell Road, Clerkenwell, are the sole agents for Ezra Kelley's watch and clock oils. They will also supply you with anything and everything for watch, clock, and jewellery making and repairing, including hands, glasses, etc., and tongs, joints, and catches.—A. B. C.

**Fancy Furniture.**—POLISHER.—By metallising I presume you mean enamelling—that is, giving a painted appearance in many colours of art shades instead of polishing or varnishing in imitation of various woods. Much artistic furniture is enamelled and decorated. If this is what you mean, it is done by mixing dry colours or pigments of the required shade in spirit or oil varnish. For instance, if a bright red is required, vermilion, or its cheaper companion, vermilionette, is carefully mixed with spirit or copal varnish, according whether a quick or slow varnish is required; spirit varnish dries in ten minutes, oil varnish requires at least six hours. If a white colour is required, use flake white; but unless you require it in large quantities, it can be bought much more cheaply at any druggist's or oil and colour warehouse than it can be made. In oil varnish enamels, Messrs. Aspinall, of the Enamel Works, London, S.E.—who advertise in this paper—are considered by some the best known makers; while for spirit enamels, that known as Foo-Chow, prepared by Donald Macpherson, Manchester Colour Works, Knott Mill, Manchester, is as good as any. Both makers prepare it in about one hundred different shades. If, however, you mean by metallising, giving to the articles a metallic appearance in imitation of brass, copper, or silver, they should be first painted any suitable colour, then varnished—which latter, while still tacky or not quite dry, should be wiped or dusted over with gold, copper, or silver bronze powder, or the whole in combination as may be required.—LIFEBOAT.

**Stain for Varnish.**—VARNISH STAIN.—Nothing is as yet known that will dissolve in spirits, similar to Bismarck, and yield a brown colour suitable for a walnut stain. The usual plan is to stain first, then varnish or polish. You may, however, add to your varnish a little brown umber (in the dry state), a dash of black, and a little Bismarck till you have the required shade. Strain through fine muslin before using.—LIFEBOAT.

**French Polishing.**—HOUSE PAINTER.—You did not put sufficient polish on your bureau: the three rubbers you gave would not be enough to fill up the grain of oak, especially if you used no "filling-in." No definite rule can be laid down as to the number of rubbers of polish required, some woods being much more porous than others; but in the bodying up the grain should be left filled, and just a little over; then set aside for some hours, or over-night, to allow for sinking. When you take it up again it would require a few more rubber of polish previous to spiriting out. If at this stage you gradually worked out the polish in your rubber by putting on a few drops of methylated spirits at a time, and worked it out fairly dry, you should leave no streaky marks for the spirit rubber to remove—only a semi-transparent film of oil, to remove which some polishers dispense with the spirit rubber as made of wadding, using instead a swab of clean soft rag, fairly moistened with methylated spirits, and pressed well in, which should be applied to the work very slightly, at first with a straight, then circular, motion, applying pressure as it gets drier. New spirit rubbers in the hands of the inexperienced are very deceptive. One is apt to get them too wet, thereby softening and tearing up the gums instead of clearing out the oil and increasing the lustre. Your chief cause of failure has been an insufficient body of polish, and trying to make the spirit rubber do what the polish rubber should do.—LIFEBOAT.

**Books on Flues, etc.**—ST. MUNGO.—The "Engineers' Practical Guide to the Fixing of Hot-Water Apparatus and Warming Greenhouse and Building" will probably contain some, if not all, of the information you require on flues, boilers, and hot-water work in general. The author of the book is John Eldridge, hot-water engineer. The book is illustrated with plans and sections; the price is 1s. only. Publisher, Spon, London.—R. A.

**Electric Belt.**—W. S. (*Cambridge*).—The clasp of the belt may be made of copper, brass, silver, German silver, or any other metal, and may be made in any form you may select, providing it forms a complete metal connection between the ends of the row of discs on the belt. The wires do not cross each other, since they are merely short pieces, of about 3 in. in length, connecting each copper disc—except one on the outside—with each zinc disc in the next couple on the inside, except one. A copper disc at one end, and a zinc disc at the other, must be connected to the two halves of the clasp. Thin pieces of steel, 3 in. in length by ½ in. in width, such as crinoline steel in short pieces, well magnetised, then sewn into a flannel belt at distances of 2 in. apart, will do equally as well as this electric belt, and will not need any connecting wires or metal clasp.—G. E. B.

**Electrical Instruments.**—N. F. M. (*Paddington*).—Complete replies to your four questions would

occupy one whole number of WORK, and would give me a fortnight's hard work. We cannot devote so much time and space to one correspondent. (1) A simple cigar-lighter may be made of a few inches of No. 24 platinum wire made into a spiral, the ends soldered into two strips of copper, and these connected to your battery. The platinum will be raised to a white heat, and will then light a cigar. Space will not allow of a sketch. (2) I cannot tell you here, in "Shop," how to make an ammeter to read from 1 up to 20 ampères. Space cannot be spared for the necessary engravings and description. (3) The foregoing remark applies to your third question, respecting an automatic magnetic cut-out to work with current up to 20 ampères. (4) I do not know the "West Rheostal," so cannot tell you how it is made.—G. E. B.

**Electric Candle-Lighter.**—A. F. E. (*London, S.E.*).—I cannot clearly understand what you mean by wanting an electric apparatus, "not more than 6 in. square, to give 200 sparks, each of sufficient size and duration to light a candle." If you want an electric candle-lighter in a small space, I advise you to get a pair of the small but powerful lithanode cells made by Messrs. Cathcart, Peto & Co., 57B, Hatton Garden, London; and get them to make for you a portable cigar-lighter, to be worked with current from those cells.—G. E. B.

**Repairing Broken Carbons.**—R. B. (*Durham*).—I do not know of a method by which broken carbon rods or plates can be cemented together and made "to work the same as if they had not been broken." You may drill holes in the carbons, and put in brass screws, fastening with molten lead. As the carbons are broken off level with the tops of the pots, you will have to get new ones. It rarely pays to repair old Leclanché cells.—G. E. B.

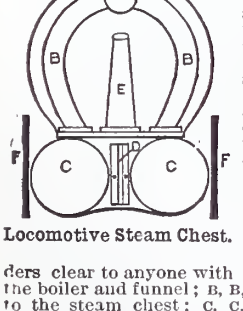
**Glass for Overmantel.**—WALLSEND.—I deal with J. M. Newton, 7, New Inn Yard, Curtain Road, London. His prices range from 1s. 9d. per foot for the small sizes mentioned by WALLSEND, to 2s. 1d. per foot for plates of 5 ft. in area. ¾ in. bevel costs 3d. per foot, measuring margin extra to the above. The silvering is good (pure silver process), and I have always been pleased with the article supplied.—B. A. B.

**Medicine Chests.**—H. F. (*Wigan*).—If H. F. wants anything specially good he should write to Betjemann & Sons, Pentonville Road, London, N. If ordinary goods are required, Betjemann, of whom I have inquired, recommend Maw, Son & Thompson, Aldersgate Street, E.C. If H. F. wishes to place orders for a considerable number, he should obtain prices from a *fancy* cabinet maker or a leather-case maker, in that case obtaining a sample for the maker to work to; or better still, devising some improvement himself. The making and lining of these goods are separate trades carried on by different people; liners abound in Clerkenwell, London.—B. A. B.

**Fish Glue and Copal Resin.**—W. J. P.—Address of dealer in the above commodities: C. W. Waters, 72, Great Eastern Street, London, E.C. This is a firm doing a big business in polish, varnish, lacquers, glues, gums, gelatines, etc. As to terms, "wholesale" will depend on the quantity you wish to purchase, no matter with whom you deal.—F. P.

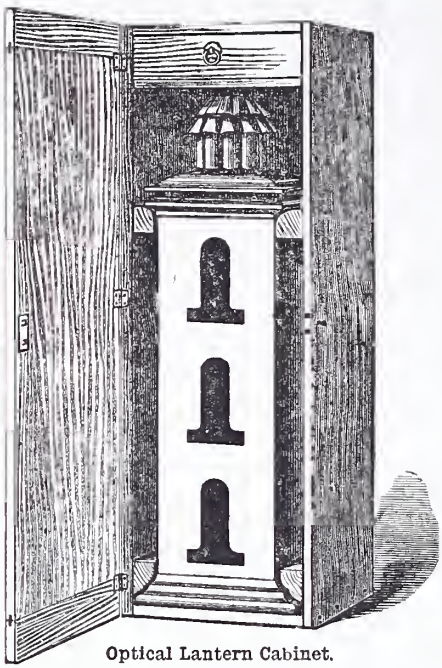
**Reflector.**—LOVER OF "WORK."—It seems unlikely that a window having a south aspect requires a reflector; but if so, it must be because the light is obstructed by buildings or trees. LOVER OF "WORK" had better try various angles until the result is satisfactory; he will then be doing as others do in similar circumstances. He does not say if his workshop is on the ground floor. This is of importance in deciding.—B. A. B.

**Steam Chest.**—READER.—(*No Address*).—The steam from the boiler, on passing through the regulator, flows to the steam chest or valve box, in which the slides for admitting the steam to and releasing it from the cylinders are placed, and by their means is permitted to act on each side of the piston. The diagram shows a cross section through the cylinders, slide-valves, and framing of an inside cylinder locomotive, with the steam-pipes to and exhaust-pipe from the cylinders. An examination of this, reference being had to the letters, will, we think, make the path of the steam from the boiler to the cylinders clear to anyone with very little trouble. A is the boiler and funnel; B, B, the steam pipes leading to the steam chest; C, C, the two cylinders; D, the slides or steam-valves; E, the exhaust-pipe, by means of which the steam escapes up the funnel; F, F, the side frames supporting the cylinders, boiler, etc.—C. E.



Locomotive Steam Chest.

**Optical Lantern Cabinet.**—F. C. (*Londonderry*) asks for a sketch of a travelling cabinet in which to pack an optical lantern. This is an article which will require to be carefully thought out by the operator himself, in accordance with the requirements of the lantern to be packed. In the cabinet shown in the sketch, the lantern is slid into the case in an upright position by means of a door at the back, which is hung with brass butt hinges, and furnished with one or two locks and a pair of handles. Some operators prefer to use pull-off hinges in order that the door can be taken off bodily when desired. Some felt-covered guides should be screwed to the sides of the case on the inside, in a suitable position, to hold the instrument in place, and keep it from moving during transit. The internal arrangements of the case will naturally depend upon the requirements of the apparatus, but at least one drawer should be set aside to contain the usual requisites of the operator, including



Optical Lantern Cabinet.

the tin or bottle of lime, cylinders, a box of matches, a hammer, screwdriver, gimlet, gas pliers, nails and tacks, a few screw hooks, some gas joints and connections, and last, but not least, a measuring tape and some useful lengths of red rubber tubing. Some operators arrange a special drawer for the lecturer's reading lamp, and another for the rubber tubing. Lantern slides must never be packed in the cabinet with the lantern; it is best that they should have a separate box to themselves. Another useful form of lantern cabinet is a shallow box with a deep lid, so that the instrument can be laid on its side, with numerous compartments in every available space between the lenses and hood to take the accessory appliance, the box being made of sufficient size to allow of the screen being laid over the lantern in order to form a soft packing. The various accessories must, of course, be tightly fitted into the compartments, which will naturally require to be cloth lined. The case should be made of straight-grained yellow pine, which may be painted with Aspinall's black or chocolate enamel outside, with "This side up, with care," in white letters on the top.—C. A. P.

**Repairing Silver Locket.**—QUÆSITOR.—This correspondent wants to repair the hinge of his locket, and from the materials he says he has, he evidently thinks of pewter soldering it. Now, merely pewter soldering one knuckle of the hinge by itself will not do: there is not sufficient hold to be obtained for security, unless a lot of solder is used, and, after all, pewter soldering is a botching way of repairing work where hard soldering is possible. If it has to be done without hard soldering, I should obtain a piece of thick silver or metal wire, fit and drill one end to form the hinge, while the other end should be hammered and spread out to fit on the bottom of the inside of the locket; by these means a strong job will be made. Why not hard solder it? There are many answers in "Shop" bearing on soldering (see WORK, Vol. I., Nos. 14, 19, 38, and 46; and in Vol. II., Nos. 76 and 104). An easy way of repairing the hinge would be to hard solder a piece of flat silver on the knuckle, and pewter solder this in. This will avoid the risk of melting the locket by hard soldering; the risk, however, is not great. There is a reply to T. N. (*Halifax*) on soldering to follow this, which will give you all particulars. If it is not clear then, please write again; and if you have an opportunity, try and see somebody hard solder any article, and note the sort of flame they obtain. Any detail overlooked in these replies will be explained on a note being sent to our Editor.—H. S. G.

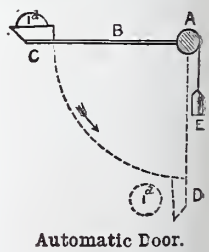
**Atkinson's Electro-Motor.**—H. J. H. (*Hackney*) and W. H. O. P. (*Homerton*).—Mr. Atkinson's electro-motor, described and illustrated on page 71, Vol. III., of WORK, can be reversed and driven as a dynamo, if the lead of the brushes is altered so that the commutator does not ruffle them; but the current obtainable from the machine when thus driven would not do any useful work. Neither Mr. Atkinson nor myself have experimented with the machine with a view to using it alternately as a dynamo and a motor, so have not determined on the gauge of wire to be wound on the armature and fields. The castings are not sufficiently massive to be used for this purpose. If you decide on trying a set of castings, wind them with No. 24 silk-covered copper wire, and get as much of this on the fields as they will hold. The direction of winding will be the same as for a motor, and the fields must be connected in shunt with the armature. At 3,000 revolutions per minute you may get a current of ¾ ampère, at a pressure of from 6 to 8 volts.—G. E. B.

**Electro-Plating.**—Z. Z. Z. (*Wednesbury*).—(1) There is no difficulty whatever in electro-plating standard silver. First swill in hot caustic alkali to remove grease, then rinse in warm water. Next, scour off all corrosion, and polish the surface. Again dip in caustic solution, and rinse. Swill next for a few minutes in weak nitric acid, then in quicking solution; again rinse, and transfer to plating-bath. Full instructions in the "Electro-Plater's Handbook," price 3s. (2) To get a higher tint of gold, raise the temperature of your gilding bath, and use another cell to your battery. Work the bath at 160° Fahr. The colour of 18 carat gold can always be given to a deposit of pure yellow gold if you have an alkaline solution of copper in working order. Deposit a thin film of copper on the pure gold, then flash a thin coat of gold over this; rinse, and dry off without scratch-brushing. Practice will give you skill in this mode of colouring gold.—G. E. B.

**Power of a Dynamo.**—SOLDAT.—The electric power of a dynamo is, or should be, calculated by its designer before it is built, and the calculations are based on the following lines:—First, the volume of current and its pressure is determined, and the machine is designed to give the required volume at the required pressure. The iron for the field-magnet cores is selected of such a size, weight, and quality as to be only half-saturated with magnetism when the full current is passing through the machine. The iron of the armature should be one-seventh the weight of the field-magnet cores. The wire on the armature of a shunt machine must be large enough to carry safely the full current, and its resistance should be one-twentieth that of the working circuit. The value of this resistance is obtained by measurement. The wire on the fields must be large enough to carry 5 per cent. of the total current, and have a resistance 400 times that of armature wire. Series machines and compound machines are of different design to shunt machines. Full instructions are given in the latest edition of "The Dynamo: How Made and Used," by S. Bottone, Wallington, Surrey.—G. E. B.

**Solenoid.**—J. G. (*Nottingham*).—You get the best result from the Fuller cells connected in two rows of three abreast, because then the internal resistance of the battery is reduced and more current is available to go through the coil of the solenoid. You may wind on more wire until the coils are three times the diameter of the plunger: each extra turn of wire in this direction will increase the pull of the solenoid. An iron tube should not be used, because this absorbs energy which should be exerted on the plunger. You will gain very little by increasing the length and diameter of the plunger. The internal resistance of your battery must be high, or you would have got better results from the six cells in series. To balance this resistance, you must wind on more wire or a finer wire on the bobbin. If you use the larger wire you must also employ larger cells in your battery. Of course, you will understand that I am working in the dark in thus advising you, for you do not give me any idea of the apparatus you wish to work in this way. A few badly-arranged or badly-fitted joints may quite hinder the working of the solenoid.—G. E. B.

**Automatic Door.**—G. S. (*Skipton*) has made a model of a chapel, and wishes to fit the inside with mechanism which will, on the insertion of a penny, cause the door to open and a figure to appear. Let A in the annexed figure be an axle, B an arm from it extended as far as space will allow, and provided with a cup, C, to receive the penny. The weight of the coin will cause the arm to descend until the 1d. falls out, as at D, when the weight, E, will cause the arm to resume its normal position. The power will, of course, depend on the leverage afforded by the arm, B. By this means nearly a quarter circle motion can be gained; and if G. S. is anything of a mechanician, he can, by taking thought, get from it the effects he wants. He will require a "fly" to retard the descent of the penny, so as to give time for his levers to open the door, push the parson forwards, and pull him back again. Unless I could see the space and arrangements of his model, I could scarcely give him further advice.—C. C. C.



Automatic Door.

**Rotating Bookcase, with Map Compartment added.**—AMATEUR.—I strongly advise you to adopt the pattern of revolving bookcase shown

here. It is square, and, therefore, there will be an equal pressure all round the central pivot; whereas I gather from the sketches of American case sent, they represent articles narrower at two sides, thus creating an uneven pressure on all parts outside the pivot. If, however, they *are* square, the width may be in excess of that required for the hooks, thereby wasting space. The English articles are made similar to Fig. 1, but are supported upon cross-shaped feet. Perhaps it may be advisable to

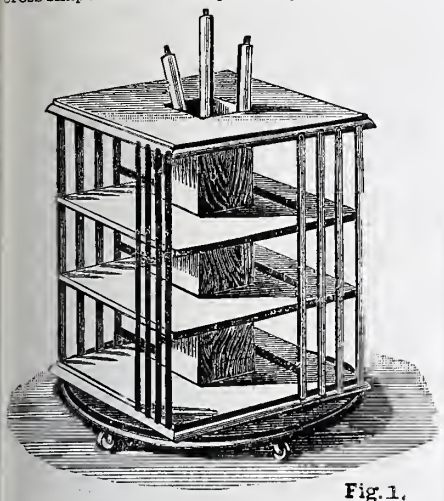


Fig. 1.

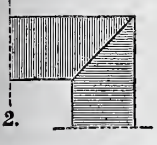

Fig. 2.

Fig 3.

**Rotating Bookcase. Fig. 1. — Bookcase, etc. Fig. 2.—A Corner of Shelves. Fig. 3.—Ditto, exhibiting the form of Joint at Mitre.**

support the body upon balls. If this is done, I recommend the cutting of a shallow groove at a few inches within, and parallel to, the circumference of the turn-table, within which you should place three or four metal balls loosely at equal distances apart. Then pivot the body to the turn-table, and the balls will revolve in the groove when the case is turned. I think it is quite a new suggestion on my part to utilise the middle space formed by middle upright boards, instead of covering it in, as is usually done. You could therein store any of your maps when rolled. Join or screw four mitred or dovetailed boards of any desired height (say, about 26 in.) to a bottom board about 2 ft. square and 1 in. thick. Shelves could be mitred up as in Fig. 2, back parts of them being tenoned into the upright boards, and mitres being joined as in Fig. 3. Upright boards could be tenoned into shallow mortises in top board, or merely screwed. Upright rails, of about 1½ in. width, should be pinned as shown, and stop-rails fastened within the case. Wood is obtainable at any timber merchant's. Oak, walnut, mahogany, or any common wood is suitable for this article.—J. S.

**Sofa-Bedstead.**—H. S. (*Birmingham*).—You ask for a settee with folding bedstead. I presume you

Fig. 3. Fig. 1.

Fig. 2.

**Sofa-Bedstead. Fig. 1.—The Sofa, exhibiting Bed-Frames being unfolded. (The narrow end Frame is separate, and would not fold, as in sketch; but it is so shown to facilitate understanding.) Fig. 2.—Catches to be fixed to narrow Frame and end Bed-Frame. Fig. 3.—One of two Sofa Bolsters.**

mean the old-fashioned sofa-bedstead. There is a distinction, but not much difference, between a settee and a sofa. All that you require is shown in the drawings. Of the construction of the sofa proper, I can say nothing more, on account of space, than to advise you to consult Indexes to Vols. I. and II. for details of joinery. To the back of the sofa is hinged a mortised and tenoned framing of a width nearly equal to that of the sofa seat. Two other frames of the same size are hinged to this, and also to each other. Be particular that they fold as shown. You must allow a sufficiently deep rebate on the inner side of sofa framing to allow the bed-frames to lay flush with the edge of the said framing. On to the outside of the end frame (which is towards the front in the sketch) there is slipped a removable frame of about 9 in. width, by means of the catches used upon shop door shutters, of which two of A (Fig. 2) are to be attached to the large end frame, and two of B to the narrow end frame. Webbing will be on top of frames. In recess thus formed in narrow end frame hinge two supports, as shown. The legs attached to large end frame are removable, and secured by means of a spiral screwing into a worm in the frame corners, under which circumstances it is advisable, perhaps, to but half-joint those particular corners. The outside of narrow end frame is to be polished. Underneath the front of it fix two dowels, which will drop, when bed is folded, into holes in edge of sofa frame at the front. When closed, a loose cushion, of 4 in. or 5 in. depth, is placed as a seat, the ends above being occupied by loose bolsters of the pattern Fig. 3. Horsehair bag underneath seat is intended for the reception of the bedding, but, if dispensed with, appearance will gain by its absence. Read my reply (see Indexes) "Press Bed." These bedsteads, as I can testify from youthful experience, are very awkward to handle, although useful articles.—J. S.

**Battery Power for Lamp.**—CORRESPONDENT.—The battery power required to light up a 10 c.-p. incandescent electric lamp will depend upon the resistance of the lamp filament, or what is popularly known as its voltage. This term is used to convey an idea of the electric pressure required to send the necessary current through the lamp filament, and to raise it to a glowing incandescent condition. The lamps vary in voltage from 12 to 120 volts. Each cell of a bichromate battery will give a pressure of 2 volts, regardless of size. If, therefore, you divide the voltage of the lamp by two, you will get the number of cells required to light the lamp, whatever its candle-power. It follows, therefore, that a lamp of low voltage will take less cells than one of high voltage. But lamps of low voltage take a larger volume of current than those of high voltage; therefore large cells, holding not less than a gallon of liquid in each cell, must be used for low voltage lamps, whilst cells of a smaller size may be employed in lighting a lamp of high voltage.—G. E. B.

**Mordey-Victoria Alternator Dynamo.**—NED.—"The electricity is produced in a Mordey-Victoria Alternator with exciter" much in the same manner as it is produced in any other dynamo. The exciter is merely a small dynamo furnishing a current to excite magnetism in the cores of the larger machines.—G. E. B.

**Drawer Supporter.**—A. M. I. C. E. (*West Kensington*).—It seems strange that so little attention has been given to the fact of the tendency of drawers in a piece of furniture to drop upon extraction. The only inventions with which I am acquainted are my own (see Index to Vol. II., price 1d.), and one of which an advertisement and editorial notice appeared in *Furniture and Decoration*, price 6d., issue for Feb. 1, 1890 (Messrs. Smith & Botwright, 6 and 7, Eldon Street, Finsbury, E.C.). The latter, although a simple contrivance in its way, is complicated when compared to my suggestion. Moreover, it is patented, whereas my idea is not patented, whether useful or not, but is (as with all I do) given to my readers to utilise as they wish, without fear of that hawk, the "patent rights," picking holes in them for so doing. I might, in justice to the "drawer equaliser," as it is called (which is made by Messrs. Bate & Kempson, 307, High Holborn, W.C.), say that, as its title implies, it *equalises* the drawer during extraction, while my invention *retains* it horizontally when *almost fully drawn out*. I am not acquainted with any cabinets fitted with drawers with either attachment.—J. S.

**Model Printing Press.**—HOPEFUL.—This is a subject which will require a separate article in the body of WORK, not in "Shop."

**Removing Stains from Marble Mantel-Shelf.**—E. L. C. (*Portland*).—Dissolve American potash in warm water, make it into a paste with whiting, and spread the mixture over the marble. If washed off in a few minutes, it will bring with it all ordinary surface stains and discolorations. Obdurate stains may take a longer time—some hours perhaps—but if left on long, the caustic potash is apt to corrode and injure the polish of the surface. Chloride of lime is another good agent to remove obstinate stains. But if smoke has penetrated right into the substance of the marble, I know no way in which it can be removed and the original whiteness restored without taking the shelf to pieces, laying the portions in wet sand so as to leave one surface only exposed, and sprinkling this over with pipe-clay. The moisture rising will generally drive the smoke stain into the pipe-clay; but in some cases this will not perfectly succeed.—M. M.

**Planchette.**—B. W. (*Manchester*).—Take a piece of ½ in. board, say, 15 in. by 6 in., mount it on four legs, with castors which will admit of perfectly free movement in every direction, and in the middle fix a blacklead (*a*), all as shown in the side view, Fig. 1, and you have planchette. To use it, lay a sheet of paper on the table, and on it set the instrument. The two operators sit on either side, and place their hands upon it, with fingers spread out and thumbs somewhat overlapping, as in Fig. 2. Planchette is secretly asked to answer questions. After a time there is an unconscious movement of the hands, and consequently of the machine (be the cause

Fig. 1

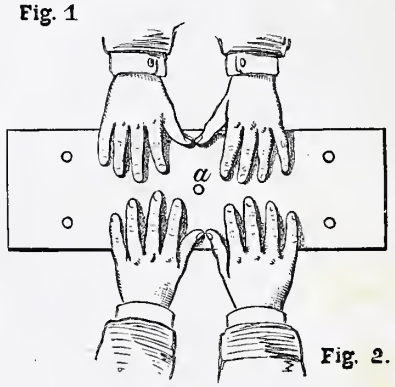

Fig. 2.

**Planchette.**

what it may), and the pencil, of course, makes scrawls upon the paper beneath it. If faith and ingenuity are present in sufficient quantities, these scrawls may be interpreted into words and answers to the questions asked. In the newspaper cutting sent by our correspondent, we read such marvels as that planchette has written a story which was accepted word for word by a magazine editor. B. W. must be told that the author of this statement is by nationality an American, and by vocation a writer of fiction, and that discount must be allowed accordingly.—S. W.

**Marine Boiler.**—R. S. (*Oldham*).—You are mistaken in saying you have such a boiler as I suggest on page 174 of No. 115 of WORK, as I describe a *vertical* boiler, and yours is *horizontal;* nevertheless, a paraffin burner may suit your purpose if properly made. As you do not give dimensions of fire-box, I cannot give you exact sizes, but these you can work to if you have the design. I assume from your sketch that the furnace has a flat top. I should advise you to make the lamp of sheet-brass, and on the plan illustrated herewith. In a horizontal fire-box there is more difficulty in obtaining a uniform air supply than in a vertical one, and special means may be required to distribute the flames equally to the tubes. Fig. 1 is a transverse, and Fig. 2 a longitudinal, section of the fire-box, the former being taken on the line 1—2 on the latter. The same letters refer to the same parts in both figures: A is the boiler shell; B, the fire-box; C C, the lamp or burner, in which are four wick tubes (D) extending about three-fourths the length of the fire-box. These holders (D), which are to contain the ordinary woven wick, have inclined upper edges, as shown, in order that the flame may be evenly distributed over the flue tubes. Air

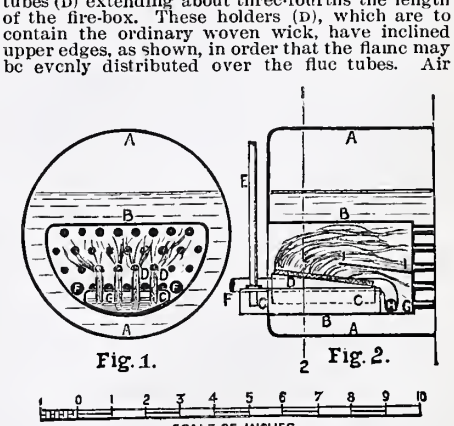

Fig. 1. Fig. 2.

**Marine Boiler.**

flows in between the wick holders from the front. The ordinary wheel arrangements may be attached for adjusting the wicks. Paraffin is supplied to the burner, C C, from a reservoir (not shown) by a pipe, E, which must of course be fitted with a cock to regulate the supply of oil. The oil should be of a high flashing temperature to obviate accidents. By

means of the cock on the pipe, E, you can adjust the supply to any requirement, from merely keeping the water at boiling point to maintaining the highest evaporation of which the apparatus is capable. In order to supply air to the back part of the burners, and prevent smoke and soot, a cross-pipe, G, is there placed, having perforations or a long slot, H, in it, directed towards the burners as shown. A baffle plate, I I, may be used to deflect some of the flames to the lower tiers of tubes, but this should be made removable until the exact requirements of the furnace are ascertained by trial. If the chimney blast does not draw sufficient air through the pipes, F, which furnish air to the cross-pipe, G, a small fan may be used to assist, or small steam jets may be fitted to the pipes, F, though this is objectionable, as steam thrown into a furnace robs it of heat.—F. C.

**Japanning.**—SOCRATES.—The reason your articles are tacky may proceed from various causes. You may have put the japan on too thickly, you may not have used the right kind of japan, your work may have been greasy when you put it on, or you may have baked the articles in an oven without ventilation. A great point depends on the oven being well ventilated to allow of the escape of the volatile solvents used in the manufacture of the japan, which are driven off by the heat. For a simple efficient oven, I should advise one made something like a gas cooking oven—square, open at the bottom; pipe running round the bottom with the ordinary pinhole jets, but instead of one outlet of air at the back, as is usual in these ovens, I should have about four 1½ in. or 2 in. holes on each side. With regard to the time to leave the articles in, that depends so much on circumstances, such as thickness of metal, size of work, etc., that I think a few experiments with pieces of tin, etc., using a thermometer and noting results, will give you more information than I could here. I am not aware of any particular method of cleaning the work; provided it is free from spirits of salts, grease, and moisture, that is enough. If in doubt as to the japans you are to use, apply to Messrs. Wilkinson, Heywood, & Clark, japan manufacturers, Caledonian Road, N., where you can get anything you require in that line. Glad to hear that you appreciate the articles on Sheet Metal Work; there are some more in hand that will probably be of still greater use to you.—R. A.

**Galvanising Brass Castings.**—J. D. (*Strabane*).—From the manner of your inquiries—viz., asking for the "receipt" for tinning nails and galvanising rivets, and the receipt for casting brass keys and "brasen"—by which I presume you mean brazing—it is very evident to me that you have not even an elementary knowledge of the things you inquire about. This being the ease, it would be useless to take up space with a lengthy reply such as your queries would involve. I can, however, give you a piece of good advice, which is this: As you are a new reader of WORK, get all the back numbers as soon as you can, and you will there find much that will be valuable to you, and possibly something on the subject you write about.—R. A.

**Cycle Parts.**—T. S. (*Morpeth*).—The St. George's Cycle Company is a reliable one. I have dealt with them for the last two years in cycle goods, and have always found them prompt in sending parcels, unless they were out of certain things, and waited for them, when two, or even three, weeks might elapse. I should never think of referring readers to any firm unless I had experience of it.—A. S. P.

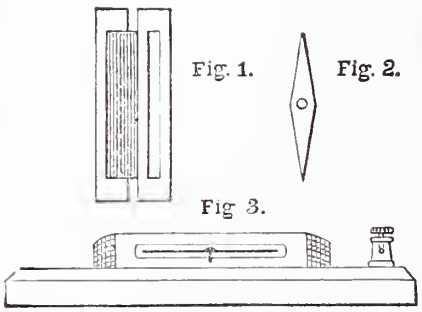
**Polish for Bookcase.**—T. F. (*Tamworth*).—As a means of keeping it clean and showing up the beauty of the wood, polishing is much preferable to varnish; but as you do not seem conversant with the *modus operandi*, I should strongly advise you to read carefully the articles, "How to French Polish" and "The Rubber in French Polishing," which appeared in Nos. 105 and 108 of WORK; also the hints on polishing constantly appearing in "Shop." Then try your 'prentice hand on something you prize less than the bookcase. You will then get an insight of what polish will do, and become possessed of rubbers that will be of great assistance when you come to the bookcase itself, which, in the meantime, might be kept clean by giving one or two coats of white polish applied with a camel-hair brush. Then, when you feel yourself more proficient, this can be rubbed smooth with fine glass-paper, and then French polished with far more satisfaction to yourself than if you take it for your maiden effort. If desired to be kept light-coloured, use white polish; if a darker or reddish shade, brown polish is used; but owing to the presence of so much carving, etc., I should advise you to use the white polish.—LIFEBOAT.

**Bicycle Parts.**—A. A. M. (*Lower Clapton*).—A. A. M. will get bicycle parts plated by numerous electro-platers in London. I may mention Brown Brothers, 7, Great Eastern Street, and St. George's Cycle Company, Islington. The latter firm will also supply him with a pneumatic saddle. I am not acquainted with the construction of such a saddle, but I know it would be a ticklish job to make by one not accustomed to such work. To enamel or paint a bicycle with enamel, scrape off all old paint. If it is difficult to remove, coat it well with methylated spirit: this will soften the paint or varnish, when it may be cleaned off, and the surface well rubbed down with sand-paper or emery-cloth. Wipe clean, and procure quick-drying *club black enamel*, 1s. per bottle, with brush. Float the enamel on quickly and evenly, as it dries very fast, taking care not to go over the same part twice. When dry, apply another coat, and you will have a good surface.—A. S. P.

**Piccolo Banjo.**—G. H. (*London, S.E.*).—The size of piccolo banjo that I generally make, and which gives the best results, is one with a 7 in. hoop and 8⅜ in. finger-board—that is, 8⅜ in. from nut to end of finger-board where it joins the hoop. This size you can tune to concert pitch one octave higher than a full-sized banjo. You could make the hoop smaller, adding to length of finger-board what you take off hoop. You will get a more powerful tone by using the sized hoop I have given. If you want to swing it about when playing, fix a piece of string or a strap on end, and long enough to slip over the wrist. Number of brackets, twelve or sixteen; width at nut, 1¼ in.; ditto at end of finger-board, 1⅝ in. The sizes given you will find comfortable to play on. If you have thin finger-tips, you might make it a shade narrower; better rather wide than having the strings too close, and not being able to stop one string without touching the next one to it. My own "Jo" is 1 in. at nut, and a little longer finger-board. If you make it longer than the size I have given, you will find the strings will not stand when tuned up to concert pitch. Size of hoop for this banjo, 9 in., and 16 in. finger-board; or 8 in. hoop, 17 in. finger-board; widths at nut and end against hoop same as piccolo; number of brackets, eighteen or twenty. You could put on more brackets, but, providing those you use are well made, you will only be adding to the weight of them without any additional advantage being derived from putting more on than the number I have given.—J. G. W.

### IV.—QUESTION ANSWERED BY A CORRESPONDENT.

**Galvanometer.**—M. (*Bishop Auckland*) writes, in reply to GALVANIC (see page 206, No. 117):—"Make a bobbin of cardboard, by gluing a strip of card on a piece of wood 2½ in. wide and ⅜ in. thick. Make the strip 1 in. wide, and fix two ends or flanges projecting ¾ in. all round. These can be fixed by gluing a strip of paper round the inside. (See Fig. 1, which shows bobbin ready for wire.) Wind three coils of No. 36 S.C. wire on the bobbin, keeping the wood in while winding, and leaving two ends 6 in. long. Also wind one coil of No. 22 S.C. wire, leaving 6 in. ends. Make a base-board 6 in. square, and fix in the centre a needle projecting upwards ¼ in., and pass this through the wire in the centre, and fix the bobbin to the base-board by a small wooden block at each end. Fix three small binding screws at one side of base-board, and fix a thick and thin wire to one, and a thin wire to one of the remaining screws, and a thick wire to the other. Make the needle 2½ in. long, as shown in Fig. 2, from a piece of steel spring, which must be heated blood-red and allowed to cool. Cut and file to shape, and drill a hole in



Galvanometer. Fig. 1.—Cardboard Bottom. Fig. 2.—Needle. Fig. 3.—Section of Galvanometer.

centre, and rivet a piece of brass in it, and drill nearly through the brass a fine conical hole. Then harden the needle by heating blood-red and cooling in cold water. Lay it across the poles of a large permanent magnet for twenty minutes to magnetise it, or insert in a coil of wire and send a quantity of jerky charges through it from a strong battery. It is now to be fixed on the needle point inside the bobbin. If it does not hang level, put a little sealing-wax on the light end to balance it. In use, the bobbin must be set N. and S.; and by using the fine wire you can test for intensity, and by the thick wire for quantity. Fig. 3 is a section of bobbin and needle. You can make the bobbin longer than 1 in. if you want to put a larger quantity of wire on. You will find this a very useful instrument; and if there is anything you do not understand, if you write again I will give you further particulars."

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—SOMERSET; A WEEKLY SUBSCRIBER; W. N. (*Lyndhurst*); R. H. (*Notting Hill*); F. H. B. (*Manchester*); C. G. (*Putney*); ELECTRICAL COMPANY; D. H. (*Glasgow*); H. C. (*Lancaster*); E. C. W. (*London, E.C.*); PLUCK DEVON; F. J. P. (*West Bromwich*); H. H. ## AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their Improved Eclipse Cameras and Outfits, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above: also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra. These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.**, post free.

***A Wholesale Dealer's Stock-in-Trade at about Half-Price.***

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

ARE universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, Frightful Dreams, and all Nervous and Trembling Sensations, &c. The first dose will give relief in twenty minutes. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

## WORTH A GUINEA A BOX.

For Females of all ages these Pills are invaluable, as a few doses of them carry off all humours, and bring about all that is required. No female should be without them. There is no medicine to be found equal to Beecham's Pills for removing any obstruction or irregularity of the system. If taken according to the directions given with each box, they will soon restore females of all ages to sound and robust health. This has been proved by thousands who have tried them, and found the benefits which are ensured by their use.

For a Weak Stomach, Impaired Digestion, and all Disorders of the Liver, they act like magic, and a few doses will be found to work wonders on the most important organs in the human machine. They strengthen the whole muscular system, restore the long-lost complexion, bring back the keen edge of appetite, and arouse into action with the rosebud of health the whole physical energy of the human frame. These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the Nervous and Debilitated is, BEECHAM'S PILLS *have the largest Sale of any Patent Medicine in the World.*

## Beecham's Magic Cough Pills.

As a Remedy for Coughs in general, Asthma, Bronchial Affections, Hoarseness, Shortness of Breath, Tightness and Oppression of the Chest, Wheezing, &c., these Pills stand unrivalled. They are the best ever offered to the public, and will speedily remove that sense of oppression and difficulty of breathing which nightly deprive the patient of rest. Let any person give BEECHAM'S COUGH PILLS a trial, and the most violent Cough will in a short time be removed.

Prepared only, and sold Wholesale and Retail, by the Proprietor, THOMAS BEECHAM, ST. HELEN'S, LANCASHIRE, in Boxes, 9½d., 1s. 1½d., and 2s. 9d. each.

Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

## A HALL LANTERN IN BENT IRON.

BY OPIFEX.

INTRODUCTION—MATERIALS—DETAILS OF CONSTRUCTION—BENT IRON SIDES—SMALL SCROLLS—PUTTING FRAMEWORK TOGETHER—LAMP-TRAY—DIPPING AND LACQUERING LAMP-TRAY—COPPER ORNAMENTS—FIXING LAMP-TRAY—METHOD OF HANGING LANTERN—SUSPENSION CHAINS OR RODS—BERLIN BLACK.

I HAVE endeavoured in this paper to describe, for the benefit of amateur workers in iron or those who desire to "try their hands" at the same, how a fairly presentable article

may be manufactured at home; and if the processes and methods employed are not "up to the mark" from the professional standpoint, yet they may be found more suited to the amateur, who does not always possess the appliances necessary to carry out the work as, strictly speaking, it ought to be done.

I believe that we should always do work, of whatever kind, in the *correct* way when we know how, and when we *can*, but I do not hold with those who will not make the attempt to produce a result merely because they may not possess the most suitable means of arriving at it. After all, the *result* is the main thing, and if we achieve a good result, then all the more credit to him who achieves it under the most unfavourable circumstances.

I make these remarks in the interest of my fellow amateurs, as I know of cases where work proposed has been unattempted and work begun abandoned, the workers being disheartened because they had not *everything* to their hands. By all means be thorough, but do not imagine that thoroughness in work depends upon the possession of every possible facility by the worker.

For example, let no reader suppose that in order to make the lantern represented at Fig. 1 a smith's forge is a *sine quâ non*, or that a complete outfit of smith's tools is indispensable, for, as a matter of fact, a good ordinary fire and a few simple tools only are required, especially if supplemented by a pair of strong hands and a fair amount of skill in using them.

It is surprising how much may be accomplished in the way of artistic iron-work with the aid of a hammer, a strong pair of pliers, a vice, a smoothing-iron, and the kitchen fire—provided always that one is on friendly terms with the *queen* of the region just mentioned.

Of course, it goes without saying that if we possess a good workshop and all those things which I have said are *not* necessary, we will be saved some trouble, and ought to be able to accomplish better results; and I am not to be understood as advocating "hole-in-corner" methods, or slovenly short cuts, but only the motto, *Nil desperandum*.

*Materials.*—This lantern is composed of iron, brass, and copper—a combination which is highly effective, and which possesses the further recommendation that it is fashionable. The main portions are of flat ribbon or hoop iron. The lamp-tray is sheet brass, and the trefoil ornaments are copper.

For the iron-work we shall require not less than 20 ft. of ribbon iron, $\frac{1}{2}$ in. by $\frac{3}{32}$ in. (or No. 14 B.W.G.), with round edges. This should be of good quality, and may be obtained at almost any ironmonger's, or of Messrs. Pfeil & Stedall, Broad Street, Bloomsbury, London, W.C.

For the lamp-tray we require one piece of sheet brass 19 in. by $1\frac{1}{2}$ in., and No. 22 B.W.G.; also a piece of the same thickness sufficiently large to form a disc—say, $6\frac{1}{4}$ in. diameter. For the ornaments we must have sheet copper of the same thickness as the brass—or No. 24 B.W.G. will do—sufficient for eight discs 2 in. in diameter, or, say, a piece 8 in. by 4 in.

We also need a supply of ball bolts. Twelve of the size shown at Fig. 6 and twelve of a size smaller will be used, but it will be well to have more than the actual number. It is not always easy to obtain these bolts, and I am unable to give any address where they can be got, except the above-named Messrs. Pfeil & Stedall.

*Details of Construction.*—Having given some idea of the kind and quantity of materials necessary to make a start, I now proceed with the details of construction.

*Bent Iron Side Pieces.*—We commence by cutting four lengths of the ribbon iron, each 3 ft. 6 in. long, for the sides of the lantern, and having an exact full-size working drawing of Fig. 2 upon some suitable surface—I always use a large roofing slate, and draw with hard chalk—we are ready to begin the work of bending the scrolls, etc.

For this we need a good clear fire and a strong pair of wire, or round-nose, pliers. Place the iron in the fire so that about five or six inches may be made red hot, and be careful not to exceed a good bright red, as if there be a strong draught in the grate the iron may be burned and spoiled.

When bright red, grasp the *extreme* end of the iron in the pliers and form the small innermost turn of the spiral; then, by gradual bending, work the iron to the required shape—applying it from time to time to the working drawing—until the point A, Fig. 2, is reached. This point should now be marked with chalk upon the iron, or if the metal is of very good quality it will bear marking with a centre-punch. Heat to bright red as before, and double the iron so that the marked point may lie upon the centre of the bend. Now grasp this bend in the vice and screw up very tightly, which operation, if carried out quickly and dexterously, will be found sufficient to form the pointed portion of the scroll A, Fig. 2. A little "humouring" of the iron, however, and perhaps re-heating, may be necessary.

The further shaping until the point B, Fig. 2, is reached, will be comparatively easy, and may be done altogether with the hands, but the reader is advised to be very careful to follow the working drawing exactly, as the whole success of the work depends upon this.

To turn the point B, repeat the operation as at A, and so on to the final scroll.

The other side pieces are now bent in the same way, applying each one to the drawing and *also to the others* as the work progresses. In this way all four will be *precisely* the same both in size and shape, which is absolutely essential.

*The Small Scrolls* (Fig. 3), which are meant to give strength and rigidity to the sides, come next.

For these, cut four lengths of iron, each 9 in. long. The spirals are turned in the same way as already described, but a pair of flat pliers will now be necessary to hold the iron with the left hand, while the shaping is carried on with the right.

See that all four are exactly the same, and in agreement with the drawing. Now place them in position as indicated at Fig. 2, and mark off the points of contact with the side pieces. Draw lines with a red pencil, etc., across the flat of the iron at each of these points, and mark decidedly in the centre with a centre-punch and hammer.

The next step is to drill the sixteen holes which are required for fixing these scrolls. This may be done with any drill available, and if the worker possesses a lathe, so much the easier will the work be to him. These holes are for the smaller, or $\frac{3}{16}$ in., ball bolts.

Insert the bolts from the inside of the small scrolls, and screw up nuts as tightly as possible on outside of sides; cut off over lengths with a pair of "nippers," etc., and rivet.

In the operation just described, care must be taken not to interfere with the shape of the side pieces, which during the fitting of the scrolls should be placed upon the working drawing.

*Putting Framework of Lantern together.*—For this purpose we require two small hoops or rings, one 3 in. in diameter (Fig. 4) for the top, and the other $1\frac{1}{4}$ in. or $1\frac{1}{2}$ in. diameter (Fig. 5) for the lower part of the lantern. For the former, it will be necessary to bend a piece of iron 10 in. long into a small hoop, scarfing and lapping $\frac{1}{2}$ in. at each end, which, if the worker is sufficiently skilled, may be welded; or they may be neatly joined by a rivet, and if the holes be slightly countersunk at each side the ends of the rivet may be filed flush, and if well done the joining will not be noticeable, and the job will be quite strong enough for the purpose in view.

The other and smaller ring may be cut from a gun-barrel pipe of the required diameter, and should be about $\frac{3}{4}$ in. wide.

Having formed these rings, mark off four equidistant points upon the centre of the outer circumference, and drill holes to suit the larger ball bolts in the larger ring, and for the smaller bolts in the ring of gun-barrel. Next drill corresponding holes in the side pieces at the points C and D (Fig. 2), or exactly at the points of contact with the rings when placed in position.

Now insert the respective bolts and screw up. Cut over-lengths and rivet as before directed, and we have the framework of the lantern complete.

*The Lamp-Tray.*—If the work already described has been carried out in accordance with the working drawings, and made upon the scale indicated, the lamp-tray will be 6 in. in diameter, or thereabouts. This is composed of a hoop of sheet brass, $1\frac{1}{2}$ in. wide, and mitred on the lower edge (Fig. 7).

Having ascertained, by exact measurement of the distance between opposite side pieces, the size of the required tray (which we shall assume to be 6 in.), cut the strip of brass 19 in. long and $1\frac{1}{2}$ in. wide; with a pair of compasses mark out the mitring in the manner indicated at Fig. 8, and cut carefully with a pair of shears—or snips, as I believe the correct term is—and finish the edges, sharp and regular, with a fine file.

To give a suitable finish to the surface of the hoop, fix a common smoothing-iron, face upwards, firmly in the vice, and using this as an anvil, hold the hoop, right side up, flatly upon it, and with the round end of a riveting hammer go over the whole surface of the brass so that the indentations shall touch each other, and striking with uniform force and even distribution of blows, a mottled appearance will be imparted, which is most effective.

Now bend the strip into a *perfect hoop*; lap the ends to a depth of $\frac{1}{2}$ in., having scarfed them with a file, and solder neatly, being careful not to allow any solder to run upon the outside of the joint.

Next cut out a disc of brass which shall fit tightly within the hoop, and fix it in position about $1\frac{1}{4}$ in. from the straight edge, or just above the mitring, of the hoop, and having well cleansed the brass with fine emery-cloth, and applied "killed" spirit in the *inside* angle of the tray, and using a very hot pointed copper bit, cause a thin stream of solder to run all round, and if the parts of the tray have been accurately fitted, a neat and strong job will be the result.

*Dipping and Lacquering.*—The appearance of the tray will be much improved by "dipping" or "colouring," and it *must* be lacquered. The former process is to impart lustre, the latter is to preserve it.

A quart of nitric and a pint of sulphuric acid, with a "pinch" of common salt, makes a good dipping bath for brasses such as the subject in hand. Mix in a glazed earthenware vessel, and when cool the bath is ready for use. Wash the brass in a strong solution of washing soda and hot water to remove all grease, and using a hard nail-brush and finest ground pumice-stone, brush the whole surface of the brass, rinse in warm water, and allow to dry. Now run a piece of *brass* wire round the tray and across it, so that it may be firmly held, and having warmed it slightly, dip it completely into the acid bath; move it rapidly with a twisting motion for a few seconds, and then rinse immediately and thoroughly in clean cold water. It should now be dried in a box containing hot box-wood or beech-wood sawdust, moving or shaking it about until all the moisture is absorbed, and being careful not to handle it without placing a piece of chamois or old silk handkerchief, etc., between the fingers and the brass. When all sawdust is brushed off the tray is ready for lacquering.

*Lacquering.*—For directions on this subject I must refer the reader to page 346, Volume I. (No. 22), directing his attention especially to the last paragraph of the article under this head.

*Copper Ornaments.*—To make these, cut out eight discs of sheet copper, 2 in. in diameter, and with a pair of compasses mark out the trefoil pattern as shown at Fig. 9. Cut out with snips, and finish edges with file and emery-cloth. To shape these as indicated at Fig. 10, we need a small block of lead—an article which is indispensable to the worker in artistic metal work. This may be about 5 in. by 6 in. by 2 in.; and if made of the shape suggested at Fig. 11 (in section), so that it may be firmly fitted in a vice, it will be all the better.

With the round end of a riveting hammer make a slight circular hollow about the size of a sixpence near the edge of the lead block, and holding the leaf portion of the copper trefoil over this indentation, beat it down with the round end of a hammer. In this way the trefoil may be easily "knocked into shape," and by slight hammering over a larger, but *shallow*, concavity in the lead, the whole may be evenly hollowed as shown.

Having prepared the eight trefoils, a $\frac{3}{16}$ in. hole should be drilled in the centre of each, when they must be dipped and lacquered as before directed; the only point of difference in the treatment of brass and copper being that the latter should have a colourless lacquer, if available, but if not, the palest gold lacquer will do almost as well.

*Fixing Lamp-Tray.* — The lamp-tray should now be placed in position, and holes having been drilled for its attachment to the four side pieces, it may be fastened up with the larger-sized ball bolts, placing a trefoil upon each, as shown in the sketch, etc.; next attach the four upper copper ornaments, and we come to the last item in the construction of the lantern: viz., the arrangement (Fig. 12) for hanging.

*Method of Hanging Lantern.* — This should be of $\frac{1}{4}$ in. round rod-iron—of some such shape as suggested—and should be carefully bent so that the "legs" may be exactly the same length and shape. The ends are turned outwards at right angles, and need not be more than $\frac{1}{4}$ in. long. These are meant to pass through two holes in the upper ring, which holes should be drilled of a suitable size at exactly opposite points in the ring.

If accurately made and fitted as shown at Fig. 12, there will be sufficient spring to allow of the ends being inserted from the inside, when the lantern should hang true upon the pivoted bearings.

*Suspension Chain, etc.*—With regard to the suspension of the lantern, a very light iron chain may be used, or a sufficient number of suspension rods made to hook into each other may be made. For the latter I give two alternative suggestions at Figs. 13 and 14.

*Berlin Black.*—All the iron portions should be treated with two coats of Berlin black, to be applied *before* joining the parts together—a direction which it might have been better to give at the outset, but which, to avoid complication, I have left to the last.

## MASONS' WORK.

BY MUNIO.

WORKSHOP — DRAWING INSTRUMENTS — GETTING OUT MOULDS — NUMBERING AND ORDERING STONES—SETTING—DOWELS, JOGGLES, CRAMPS —WINDOW-SILLS—YORKSHIRE PAVING AND KERB.

*Workshop.*—When a building is to be erected, containing a quantity of dressed stones, it is customary to build a shed, in which the stones are worked. This is generally open at the front, about 8 ft. or 10 ft. wide, and of sufficient length to accommodate the number of workmen which will be required. Bankers formed of large stones, or piles of bricks with a stone on the top, are erected on which the stones are laid while being worked. The shed should be as near the building as convenient, and there should be sufficient space near it on which to lay the stones as they come from the quarry.

A workshop should also be provided, in which a table or large drawing-board is fixed, on which the working drawings are made. These drawings are made full size generally, and as they should be thoroughly accurate, it is very important that a mason should be a practical draughtsman.

*Drawing Instruments.*—The instruments required for making the working drawings are a large square, set-square, straight-edge, chalk line, strong needle pointers, joiner's compasses, with guide and screw for fixing the legs, and beam compasses. For any drawings which may have to be made on paper, a large drawing-board, T-square, set-squares, and a set of mathematical drawing instruments will be required.

*Getting out Moulds.*—When the plans and detail drawings for the building have been received from the architect, a full-size drawing of such stones as require a mould for working them is made on the drawing-board, and from this the moulds are made. The best material for the moulds is thin sheet zinc. This must be tacked down over the drawing, and the lines marked upon it. The straight lines can then be cut by a steel scriber, and the circular lines by the point of the compasses. Figs. 40, 41, and 42 are detail drawings of a doorway, a ventilator, and roof corbels, from actual work, and from which the mason would make the working drawings and get out the moulds. Four moulds would be required for the doorway: one for the ventilator, one for each corbel, and one for the gable coping.

*Ordering and Numbering Stones.*—After the working drawings and moulds have been made, a list of the stones required in the building should be made out and sent to the quarry. Each stone, or group of stones, should have a number or mark set opposite to them. This should be marked on the stones before they leave the quarry, and if the same mark is put on the mould, there will be no trouble, when the stones arrive on the works, in selecting them for their place in the building. They should be numbered in such order that the stones which are required first should be sent in first, and this should also be attended to in working them, as it is much preferable to take them direct from the bankers to the building, than to have them lying about and liable to be damaged. The list should have the length, breadth, and depth entered in separate columns, marked at the top, as it is essential for the quarryman to know which is the bed of the stone, in order that he may cut it properly in the quarry. A copy of the list must be kept on the works for reference. When any stones are required of irregular form, a mould is sent to the quarry, to which they are roughly shaped, in order to save unnecessary carriage and extra labour in working.

*Setting.*—The setting or fixing of dressed stones is an operation requiring great care and skill. The stones are set with fine mortar, and in some cases oil putty is used, but as the pores of the stones sometimes absorb the oil, it discolours them. It should not be used for Bath stone; the best material for setting this stone is washed putty mixed with the stone dust. The stones should be plumbed on two faces and set straight on the outside face by means of a rule or line. In setting copings, cornices, etc., they should be raked or lined to each other by means of a long rule, and the top beds levelled. All stones should be solidly packed up at the tails with pieces of slates; they should be beaten down with a wooden mallet. The mallet for Bath stone should be of soft wood, or the stone will be bruised or stunned.

The joints should be thin, but there should be sufficient mortar between them to form a bed. In setting detached columns or pillars, a sheet of 4 lb. lead should be laid on the joint to within an inch of the edge, and the remainder formed of putty. This will prevent the edges of the stones being chipped when the weight comes upon them. Dowels should also be inserted between the stones.

In setting short piers between openings, where the inside is walled with rubble or bricks, the inside joints should be made as thin as possible, to prevent any settlement inwards, and it will sometimes be necessary to stay them till the heads are on, in order to obviate this.

In setting thresholds, window-sills, etc., they should be bedded solidly at the ends, and left hollow in the centre, or they will be liable to be broken when the work settles. When window-sills cannot be got in one stone, they should be in three stones; and if there are mullions in the window, the joints should be under a mullion.

In fixing mullions, tracery, etc., which require supporting till the whole are set, strong pieces of wood should be fixed across the openings to which they are temporarily fixed, till the whole window is set.

As the work is carried up, all projecting stones, angles of doorways, etc., should be cased with wood, to protect them from injury while the work is going on; and should any portion of a stone be broken off, it may be fixed by a solution of shellac dissolved in naphtha (by heat) till of the consistency of treacle.

For preserving a Bath stone front from

dirt, stains, etc., while being built, it is recommended to coat it with Bath stone dust, mixed with sufficient lime to make it adhere, and water, as it is built.

In setting spires, chimneys, and other objects built in courses at a high elevation, each course is fitted together on a level surface before being sent up, so that no cutting or paring is required after they are hoisted.

Bond stones should be laid on the tops of door- and window-heads after the walls are levelled up to them. There should also be bond stones under the ends of window-sills.

*Dowels, Joggles, and Cramps.*—Dowels are tenons fixed in the beds of stones to prevent them sliding upon each other; they are made of copper, bronze, wood, iron, and slate. Iron is not a suitable material for them, as if any dampness gets to them, it causes the iron to oxidise, and sometimes splits the stone. When iron is used, it should be tinned or galvanised. The dowels should be accurately fitted into the mortises cut to receive them, and to ensure their fitting properly the mortise hole should be cut in the mould, when it can be accurately marked and cut in as the stones are dressed. They are used in mullions, pinnacles, etc. Joggles are tenons formed on one joint of a stone, with a corresponding mortise formed on the adjoining stone; but as this causes a great waste of stone, joggle dowels are often used, a mortise being cut in each stone. They are used in jointing stone work of copings, parapets, etc.

Weather or weathered joints are those in which the under bed of the stone is notched upwards, leaving a piece of the stone projecting over the joint below, to protect it from the weather. They are used in gable copings, buttress slopes, etc.

Cramps are used for securing stones firmly together; they are made of copper and iron. When iron is used, it ought to be galvanised or tinned to prevent corrosive action. They are formed of flat bars turned down at the ends, and fixed in grooves or mortises cut in the stones; they are sometimes run in with melted lead, and sometimes with Portland cement. They are used for fixing the top stones of parapets, copings, etc.

Copper chain cramps are used in spires, chimneys, etc.; they are fixed in grooves cut in the beds of the stones.

*Window-Sills.*— Window-sills should be chamfered, or sloped from the front of the frames, to throw the water off, and the top bed on which the frame rests should be checked or rebated at the outside to prevent wet being driven in, the wood frame being correspondingly rebated at the back. In large windows with lead or iron lights a hole should be drilled through the sill from the inside, and a copper pipe brought through the wall to carry off the condensed moisture which forms on the glass. When the sills project in front of the face of the wall, a throating should be cut in the under

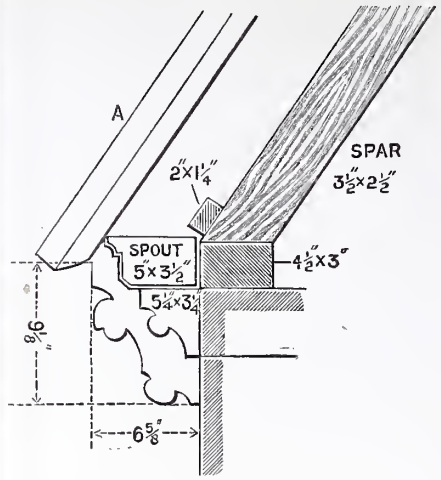

Fig. 42.—Section of Corbels, etc.—A, Corbel Coping.

bed to prevent the wet from running down the wall. The throating is a semicircular groove about ¼ in. in diameter.

Projecting string courses, copings, and all other stone work which projects from the face of the wall should be throated.

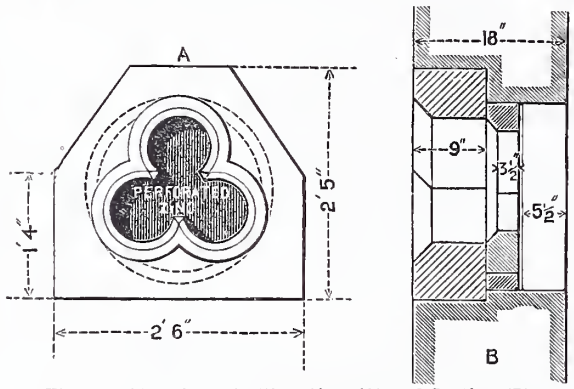

Fig. 41.—Ventilator in Elevation (A) and Section (B).

*Yorkshire Paving and Kerb.*—Yorkshire paving or flagging is of three kinds: self-faced, tooled, and polished flagging. Self-faced flagging is natural or quarry-faced; tooled flagging is tooled on the face; and polished flagging is boasted level on the face and rubbed or polished. The flags are from 2 in. to 4 in. thick, according to their size; they are selected into courses, and the edges jointed and squared. The joints should be kept square from the face for 1½ in. or more in large-sized flags; they should be bedded down solidly on dry sand, with a trowelful of mortar at each corner; they are jointed with fine mortar, and when laid outside for footpaths, etc., the joints should be pointed with Portland cement. They are laid level on the surface by means of a long rule, and raked to level pegs driven in at each side of the floor.

Paving is sometimes laid hollow on sleeper walls; it is then bedded in mortar and levelled on the surface.

Kerb is used at the side of a footpath and round area gratings, etc.; it is tooled or boasted on the top side and edge, and bedded and jointed. The joints are sometimes dowelled; it is bedded down solidly on mortar, and the joints made with fine mortar or cement. Where there is much traffic, granite kerb is sometimes used. The kerbs round area gratings are rebated for the grate to lie in.

Dressed kerbs are also fixed under iron palisadings and railings; they are tooled on both faces, and the top bed is chamfered or rounded. The holes for the rails are drilled after the kerb is fixed, and the rails run in with melted lead. Hearths are from 1 in. to 2 in. thick, boasted on the face, and polished; the edges are squared and jointed, and they are laid on the ground floor on solid foundations of brick or rubble work, and on trimmer arches on upper floors; they are made from 16 in. to 20 in. wide, and should be at least 6 in. longer than the width of the stove grate. Back hearths are laid behind hearths for the stove grate to stand upon.

Thus far the principal points and details in the manual work that is done by masons have been described and placed before the readers of WORK, briefly, it is true, but at sufficient length to afford assistance to the young professional, and also to give amateurs a fair insight into it if they are interested in it. I have, however, yet to deal with staircases and the various arches used in masonry, but the consideration of these must be left for my next and last paper.

It is not to be supposed that the amateur workman at home will find much attraction in masonry, but on the principle that all knowledge of a practical kind is useful, it is desirable to have a tolerably correct notion of the way in which every kind of handiwork is done, that if any particular kind of work is being done at one's own place, the person for whom the work is being executed may be able to form some idea as to the manner in which the work is being carried out, whether well or badly. The amateur in the colonies, however, will sometimes have to do a little stone-working for himself, if it is to be done at all, and he, at all events, will find the papers useful.

## A CONTINUOUS-MOTION DRILL-STOCK.

BY FRANCIS CAMPIN, C.E.

Action of Reciprocating Drills — Ratchet-Drills—Conversion of Reciprocating Circular and Continuous Circular Motion.

Every mechanic, amateur or professional, has experienced the inconveniences that are inseparable from the use of reciprocating drills, whether used with the bow or in an archimedean stock. To obtain anything like a true hole is impossible, and yet no work can be put together without holes, and sometimes a great many of them. Holes untruly bored are also often responsible for the breakage of screwing taps, and thus the reciprocating drill is the cause of much damage, loss of time, and disappointment. With this form of drill there is no real cutting of the material; it is merely a matter of scraping, and most frequently with the scraping edge at a very bad angle for working.

A drill with a true cutting edge will, of course, only run in one direction, and, therefore, what is required for small purposes is a hand-stock that is capable of converting alternate rotary motion into continuous rotary motion. Of course, continuous motion can always be obtained for drilling where a lathe is accessible, but this is cumbrous for small work of the charaeter we now have in view. A ratchet brace also is not suitable for small work, and is, moreover, too slow in its action, especiallywhere very light cuts have to be taken. What is required, then, is a stock which will give continuous motion in one direction, and any rapidity that may be required, and to attain these ends the apparatus shown in the annexed illustrations has been designed. Fig. 1 shows a section taken just behind the driving ratchet-wheel, and Fig. 2 a longitudinal section along the centre line of the drill shaft.

The drill shaft, A, is made with an ordinary socket, cut away at *i*, as shown, to receive the back end of the drill at one extremity, and at the other it is fitted with a handle, G. The handle is shown broken off to save space, and its posterior end is shown in longitudinal section at H. Upon the shaft, A, a fly-wheel of disc form, B, is secured by screws, *k*, *k*, the points of which enter holes drilled in the shaft to receive them, and thus cause the wheel to revolve with the shaft. The weight of wheel, B, will, of course, depend upon the heaviest class of work for which it is proposed to use the tool.

A ratchet-wheel, C C, is fastened to the fly-wheel, B, by means of screws, *d*, *d*, etc., and turns when driven by pawls, *c*, *c*, carrying the fly-wheel round with it. The pawls, *c*, *c*, are hung upon pins, *m*, *m*, screwed into the division *o o* in a spring barrel, D D. It is important that the pawls, *c*, *c*, should be set diametrically opposite each other, to prevent inequality of bearing of the drum, D D, on the sleeve, F, upon which it is mounted, to revolve freely. It will be obvious that, so long as the two pawls act together, there is no pressure on the sleeve, F (except the nominal weight of the spring barrel, D D), and, therefore, no noticeable wear on the barrel at its bearings. The barrel is kept up to the fly-wheel and ratchet-wheel by a collar, E E, brazed, or otherwise firmly fixed, to the sleeve, F, while the sleeve itself—which runs easily upon the drill shaft, A—is longitudinally secured by a nut, *n n*, screwed on to shaft, A, and contained in a cavity in the end, H, of the handle, which is screwed on to the handle body at *g*.

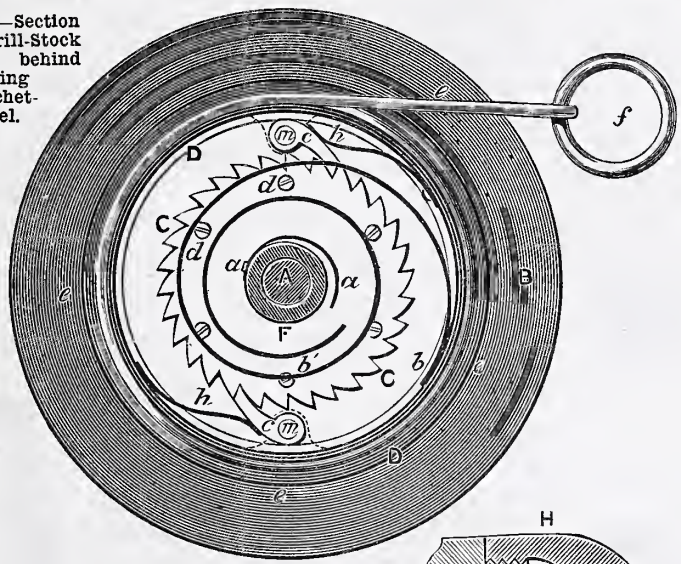

Fig. 1.—Section of Drill-Stock just behind Driving Ratchet-Wheel.

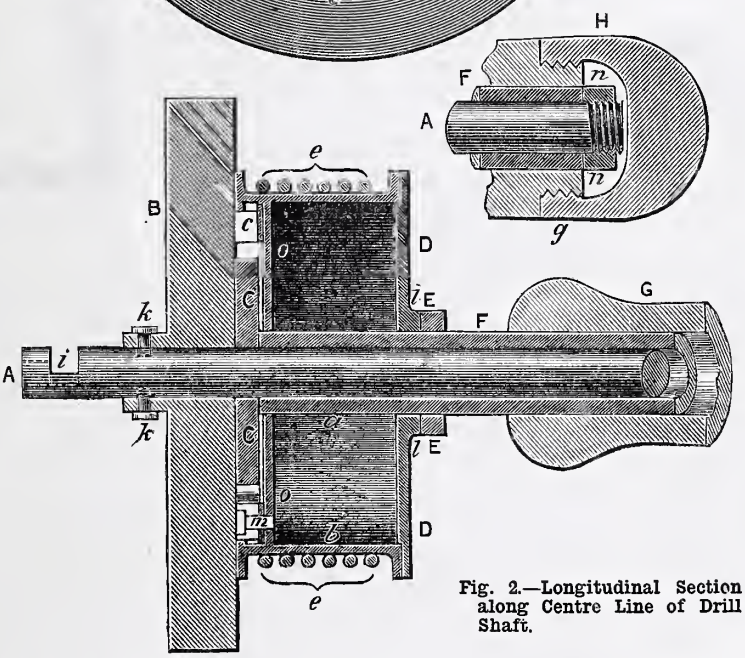

Fig. 2.—Longitudinal Section along Centre Line of Drill Shaft.

The barrel, D D, contains a strong clock spring fastened to the sleeve, F, at *a*, and to the periphery of the barrel at *b*. In Fig. 1, only the ends of the spring are shown, in order to allow the parts beyond to be clearly seen. To the barrel are also attached light springs, *h*, *h*, to hold the pawls, *c*, *c*, in contact with the teeth of the ratchet-wheel, C C. One end of a piece of catgut, *e e e*, is fixed to the exterior of the spring barrel, round which it is coiled for a few turns, its end being attached to a finger ring, *f*.

The apparatus is easily taken to pieces, if required, for cleaning or other purposes. When the screws, *k*, *k*, have been withdrawn and the nut, *n n*, all the parts will come asunder. The collar, E E, instead of being brazed on to the sleeve, F, may be cast in one piece with it. In order to adapt the stock to different kinds of work, several fly-wheels of different weight may be made to fit it, so that they will be interchangeable on the same drill shaft.

In use, the handle, G H, of the stock is held in the left hand, then on pulling the catgut, *e*, by finger ring, *f*, with the right hand, the barrel, D, is caused to revolve, and by the pawls, *c*, *c*, carry the fly-wheel and drill shaft round with it; at the same time, the spring, *a b*, is wound up. On letting the catgut loose, the spring re-winds it on the barrel for another pull, and during the re-winding the momentum of the fly-wheel, B, maintains the forward revolution of the drill, the pawls, *c*, *c*, passing meanwhile backwards over the teeth of the ratchet-wheel, C C, and thus a constant rotation of the drill in one direction is maintained. The drum and ratchet arrangements, drill shaft, etc., are shown about natural size. If a very high velocity of revolution is required, higher than can conveniently be obtained with the catgut coiled on barrel, D, the boss, *l*, of its back-plate may be made longer, and used as a barrel on which to wind it, which, for a given velocity of hand, will increase the number of revolutions three times. If it is desired, this contrivance may be fixed in a frame and clamped to a bench, to leave the left hand at liberty to manipulate work which is being drilled.

I am inclined to think that the advantages to be derived from a drill-stock of this kind will be obvious to every mechanic who is in the habit of using drills, and that the old hand-stocks will eventually be superseded by this new form. It is never safe, however, to speculate with any particular degree of confidence on what may happen with regard to new tools and appliances, which are departures from the beaten track, and it is often some time before a good thing is taken into favour.

## A CHEAP CAMERA LUCIDA FOR MICROSCOPIC SKETCHING.

BY H. B. S.

Two Methods of Making: In Sheet Zinc—Materials Required—Method of Making. In Brass: Materials Required—Method of Making—Adjustment to Eye-Piece of Microscope.

Those readers of Work who have a microscope will know what a camera lucida is used for. It is similar to an ordinary camera lucida, but on a small scale, and is fitted to the eye-piece of a microscope to reflect the image, and thus allow of its being sketched. There are many kinds of camera

lucida sold, and the price varies from six shillings to thirty shillings. The two I describe will cost not more than a few pence.

There are two methods of making a camera lucida which I have tried: first, in sheet zinc. Materials and appliances required:—Piece of thin sheet zinc 3 in. by 1¾ in., a pair of scissors, a pair of compasses, and one thin glass circle, same as used for covering objects.

Mark out a circle on the sheet zinc of about ¾ in. diameter, and within this a circle of ½ in. Cut out inner circle. Connect it as shown (Fig. 1) to the strip 3 in. by ½ in.; cut out with scissors. Take a ruler or any cylindrical object a trifle smaller than eye-piece of microscope, and bend the strip around it; it will then form a ring which will fit on to eye-piece. Now bend up the connecting bit slightly, touch around the circle with gum or glue, and having cleaned the cover glass, drop it on; if thought necessary, a ring of black paper may be put on over cover glass to keep it in its place (Fig. 2). Now allow

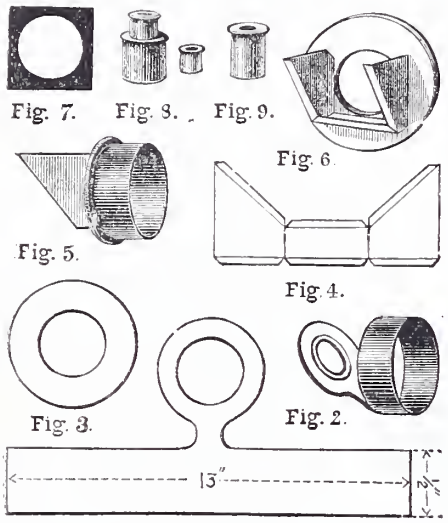

Fig. 1.

Fig. 1.—Plan of Camera Lucida in Zinc. Fig. 2.—Zinc bent into shape. Fig. 3.—Brass Ring. Fig. 4.—Pattern for Camera Lucida. Fig. 5.—Material bent into Box Form. Fig. 6.—End View. Fig. 7.—Cover Glass. Figs. 8, 9.—Eye-Pieces.

to dry, then place it on eye-piece of microscope, place the microscope horizontal, and having an object at stage of microscope, look down at cover glass, and see if the object is visible; if not, move the circle upwards or downwards until the object is visible, when the glass will then be at an angle of 45 degrees with tube of microscope. This adjustment and the sketching which may be done must be done in a dark room, when the lamp is used for direct illumination. Sketching cannot be done in daylight.

The second method is a little more difficult. A little thin sheet brass, shears, a soldering-bit, solder, brace and bit, and file will be required.

Measure diameter of eye-piece, and cut out a strip of brass long enough to make a ring that will just slide on to eye-piece; bend it round and solder, or maybe you can get a bit of tubing to fit; it must fit tight, and may be ½ in. or ¾ in. wide. Next cut a circle a trifle larger than the ring, drill a ½ in. hole in it (Fig. 3), and solder on to the face of the ring. Next prepare a piece of the sheet, and cut out as shown in Fig. 4, the angles exactly at 45 degrees, and bend up into the shape of a box, open at top and ends; turn down pieces for soldering inwards, also pieces on other side intended to hold glass, and solder it directly on to the face of the metallic cap you have made (Figs. 5 and 6).

All that is now required is a cover glass mounted between two pieces of black paper (Fig. 7). Let it rest in the box.

The first described will fit any eye-piece, but the second one will only fit the eye-pieces in which the front part may be detached (Fig. 8). It will not fit those having a milled edge larger than the rest of the eye-piece (Fig. 9).

I have made both kinds of camera lucida, and they are as good as any to be bought. The cover glass being so very thin, there is no double reflection, as you see in a thicker piece of glass.

## MEANS, MODES, AND METHODS.

### To make Lime in Small Quantities.

Few who live in the country have not felt the difficulty of procuring small quantities of quicklime. In my own case, for instance, I have to send seven miles for it, which takes a man and horse the best part of a day, when I want, perhaps, but sixpennyworth of lime. I was bemoaning this fact to a lady friend of much practical common sense, when she astonished me by saying that when they wanted to whitewash the kitchen or any small piece of work, they put limestones in the kitchen fire and burned their own lime. On my return home I put the matter to a practical test, and lo! it was so. To use the words of my man, "I won't be without lime now when I want it." J. L. D.

### Substitutes for a Short Screw.

Any of my readers who have observed a properly mounted grindstone will see that the stone is clamped between two flanges, one of which abuts against a shoulder in the shaft, whilst the other is pressed against the stone by means of a nut threaded on to a screw cut on the axle.

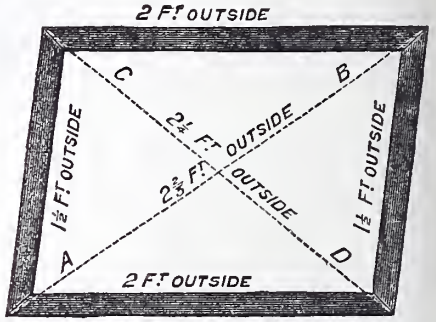
I wanted to mount a stone in this way, but had not dies of the exact fit for the axle. I consequently designed an efficient substitute for the screw as follows: I first put the stone on the axle, and marked the outside of the outer flange; then, a ¼ in. outside that I drilled a hole across the axle to take a ¼ in. steel pin. I next procured, as a washer, a back nut used by gas-fitters, which was ⅜ in. thick, and fitted nicely over the axle. I then filed nicks on the opposite sides of the washer ⅛ in. deep, and sloped the washer from the bottom of one nick to the top of the other. When the stone, flanges, washer, and pin were put in place, the washer, thus treated, acted as two half-threads of a double-threaded screw, and held the stone quite securely. J. L. D.

### A Simple Way of Testing the Accuracy of Framework.

If there is one thing more tantalising than another to an observant person, I really believe it is to notice any such article as a picture-frame made out of the square. A certain picture-frame in my possession tormented me by its apparently bad workmanship, and I set about testing the angular accuracy of its four corners, in order to settle all doubts and ease my mind; and while doing so, was told by a looker-on of a simple means of acquiring the object in view. The advice was to measure the distance between two opposite corners of the frame crossways, allowing the string to pass over the centre of it, as per dotted line A B or C D, and then to place the string or measure between the two remaining corners. If this course is adopted, and both distances coincide in measurement, all is well; if not, it will thereby be discovered that something is wrong somewhere.

In the diagram an imaginary frame is drawn to a degree of inaccuracy so decidedly exaggerated that the most unfortunate possessor of distorted vision would hardly find it needful to resort to any mechanical method for the object of obtaining the truth as to the irregularity of its angles; but the sketch is so delineated in order to convey a better and clearer understanding of the means of testing, and a comparison of the variations of distances between the opposite points of the several parts.

It will be readily understood that in the case of a careless apprentice or workman making the mitre on any particular rail of the job wrongly, it would be a comparatively easy matter for him to mitre the adjacent rail in such a manner that it would perfectly fit it, although, however, the result would be the formation of an improper angle by the unison of the two rails.



Badly-made Frame with Faults exaggerated.

I am not aware whether this method is used among wood-workers—one must be a curiously well-informed being to not be ignorant of some things in this busy and knowing world—but it is a common practice among wire-workers when they wish to discover whether the squareness of their work is correct; and probably I may have to allude to this note during the course of my papers on Wire-work.

It must be obvious to all who have the intelligence to perceive the simplicity and efficiency of this method—and who has not?—that the application of the same would answer in every respect equally well for the determination of the accuracy of any kind of framed work, such as doors, etc., by either measuring within or outside the frame; in the case of a four-styled door, adopting the latter course, and in the instance of a door with one or more cross rails between the upper and lower styles, using the former.

If half of the difference between the two distances across the frame upon the lines A B and C D respectively be taken and added to the shorter measurement, that will give the correct length the work should be diagonally across from corner to corner either way—that is to say, supposing A B is 2 ft. 6 in. long, and C D 3 ft., the difference will be 6 in., one half of which, if added to the shorter distance (2 ft. 6 in.), will give the correct measurement, viz., 2 ft. 9 in. J. S.

## HOW TO MAKE A QUARTER HORSE-POWER STEAM ENGINE.

BY F. A. M.

### The Piston, Slide-Valve, Ports, and Cylinder Covers.

The Piston Rings—Piston Cover and Body—The Piston-Rod and Nut—The Valve-Face—Valve-Box and Cover—The Ports—Screwing the Parts together—Turning and Threading the Stuffing-Box—The Slide-Valve and its Rod—Screws for Securing the Cylinder Covers.

We may now undertake the piston and rod, shown in detail in Fig. 5 (page 260). Begin with the casting for the brass packing rings; chuck this by the outside, and bore it out. It measures $1\frac{3}{8}$ in. diameter inside on the drawing, but, as it will have to be compressed, we will bore it out $\frac{1}{16}$ in. larger than this. Drive it on to a mandrel, and turn the outside to $2\frac{1}{16}$ in. diameter; turn the edges and part it in two, so that each ring shall be $\frac{1}{4}$ in. wide. By turning the edges of the rings at one chucking, you ensure their being parallel. Now take them to the vice, the jaws of which must be protected with lead "clams"—*i.e.*, sheet lead about $\frac{1}{8}$ in. thick, bent over the jaws, to prevent them from marking brass or other work. We have now to file and scrape the edges of these rings till they are perfectly flat, and that without destroying their parallelism. We shall require a perfectly flat surface of some kind; perhaps the scraped surface of the lathe-bed might do, though it will not be very correct, or a piece of plate-glass is sometimes used. Much better would it be to obtain a reliable face-plate or surface-plate—one 3 in. by 5 in. will do for the work we have in hand; if of this size, it will do to correct the bed-plate facing on which the slipper guide works, as a 3 in. plate will go between the flanges. Get some Venetian red, and mix with machine oil in a little flat tin box, which you will keep ready at hand. Smear a very little of this "marking" on the face-plate, equally, all over it; then, when the rings are rubbed upon it, you can see those points which touch the surface, and at the same time you can feel on which parts it rocks. To hold the rings while being filed or scraped, take one of them, and, laying it upon a bit of wood, draw round it with a pencil, and hammer a few small nails into the wood upon the line, so that you can replace the ring on the wood between the nails, that they may prevent its slipping while you file it; the heads of the nails will be knocked down a little lower than the upper edge of the ring, that they may not interfere with the file. Callipers are sure to spring slightly, and, as the rings must be perfectly parallel, make a solid calliper by filing a notch in a bit of sheet iron to act as a gauge of width. File up and scrape one edge of each of the rings till they bear well all over on the face-plate; then file the notch for the gauge, trying it on the rings all round till it will almost go on at the smallest place; then bring up the other surface of each ring true, so that the gauge will go on equally tight all round. Handle the rings tenderly, as they are very easily bent and bruised; you could probably squeeze them flat with the grasp of the hand, and if they are dropped on a piece of iron, or a tool thrown down on one, it will get a nasty bruise, and require to be tried on the face-plate again. Screw a ring gently in the vice in the lead clams, one edge projecting about $\frac{1}{4}$ in., and take the hack saw to cut it across; the cut should not be straight across, but oblique, because then the edges of the ring are not so likely to wear grooves in the cylinder. The rings must be cut twice, about $\frac{3}{16}$ in. apart, so as to remove about $\frac{1}{4}$ in., leaving an oblique gap $\frac{1}{4}$ in. wide; this is necessary to enable us to close the rings to get them into the cylinder. Now take the cover of the piston; chuck it, face one side, and bore a $\frac{5}{16}$ in. hole through the middle. Chuck the body of the piston, hollow side out; true that side, and bore a $\frac{5}{16}$ in. hole through. Lay aside these two parts, and take a piece of round mild steel (such as Bessemer), $8\frac{1}{2}$ in. long and $\frac{1}{2}$ in. diameter; centre this, and turn it down to $\frac{3}{8}$ in. full. Turn down one end to fit tightly into the body of the piston; cut a $\frac{5}{16}$ in. Whitworth thread on the end of this part, and make the brass nut which goes on there. Now drive this end of the piston-rod into the body of the piston, and put on the nut, screwing it hard up to secure the piston body on the rod; put all between the centres, and turn up the piston body. Take the piston cover and scrape up the inner surface; take off the nut from the end of the piston-rod, put the piston cover on in its place, and put the nut on again to secure it, screwing it on tightly. Now take the brass packing rings, and try whether they will fit into the groove; if too tight, turn off a little from the side of the groove which is part of the piston; if too loose, take off the nut and piston cover, and turn away a little from the face of the piston against which the cover fits. The width of the groove must be such that when the rings are in position, and the nuts screwed hard up upon the piston cover, the rings will be held tightly enough to stand turning; we must turn the outside of the rings again, because when they are compressed into the cylinder they will no longer be exactly round. First, turn the outside diameter of the piston body and cover to exactly fit into the cylinder; when trying it into the cylinder, be careful to wipe the turning dust off and have the bore of the cylinder quite clean, or you may be deceived. It is better to pass the piston-rod through the stuffing-box in the cylinder cover when trying the fit of the piston, because that will keep it from getting askew in the cylinder; therefore, at this stage it will be well to finish the piston-rod to size. Use the brass gland as a gauge of size, and, putting in a very sharp tool, with a light cut reduce the piston-rod till the gland will almost go over it; then take a worn, smooth file, and use that on the rod as it turns in the lathe till the gland can be pushed over it with some difficulty. Now take a smooth file and "draw-file" the rod, rubbing lengthways from end to end, whilst the lathe is at rest, so as to lay the grain of the scratches longways of the rod, and remove all circular scratches, which would rapidly wear out the packing, besides greatly increasing the friction. The gland should now slide freely over the rod from end to end, and in trying the fit of the piston in the cylinder the cover would be put on, and the piston-rod, with piston on it, would be passed in from the back end. The piston-rod, passing through the cover, would keep the piston true and level, so that the fit can be observed. When the fit of the piston in the cylinder has been adjusted so that it will pass freely up and down in the cylinder, take off the nut and cover from the piston, and put it just inside the cylinder, the rod passing, as before, through the stuffing-box in the front cover. Now take one of the packing rings, and, compressing it slightly with the fingers, press it into the coned-out mouth of the cylinder and over the body of the piston; now the other ring; now the piston cover and nut (but do not screw up the nut). On pressing, or gently driving, the piston forward, the rings will gradually close till they come to the parallel part of the cylinder. Try drawing the piston up and down, tighten the nut, and take out piston and rod. Now you will see the rings were not bearing very equally all round; there will be bright spots showing where they rubbed hard on the cylinder. Put the piston as it is in the lathe, and take a light cut over the rings; put piston in the cylinder, loosen the nut, and pull it up and down; fix nut, take out, and examine. The bright marks should now show all round the rings. If, however, the piston rubs hard in the cylinder, turn a little more off the rings, till there is only enough spring left in them to hold up tight without causing too much friction. One thing more remains to be done to the piston. The surface of the piston cover against which the rings rest is scraped, but the corresponding surface on the body of the piston is left from the lathe tool. This surface must now be got up with the scraper, taking off so much metal that the rings shall be released and able to move, even when the nut is tightened upon the piston cover; yet too much must not be taken off, for the rings must touch both sides of the groove in which they lie, and still not be pinched so tightly that they cannot expand. The shape of the piston body makes it impossible to use the surface-plate to try this last annular surface, but one of the rings can be used. Rub the edge of one of the rings with the marking, and rub the ring on the piston surface: thus you will be enabled to scrape it up. A little reflection will show that it would not have been sufficient to prevent leakage between the packing rings and cylinder, if we allowed the steam to get between the edge of the rings into the groove of the piston, and so out the other side; moreover, we must take care that, when we put in the rings, the two cuts do not come together. The cut place on one ring should be at an angle of 90 degrees (at right angles) with the other; then the steam cannot pass, and the rings will press equally all round the inside of the cylinder. The piston being now finished, all but the cross-head end of the rod, it should be oiled and put away.

Let us now undertake the valve-face of the cylinder, valve-box, etc. File up the valve-face, keeping it parallel with the bore of the cylinder by means of callipers, measuring from inside the bore to the valve-face, or laying this face on the surface-plate, and trying with a square whether the flanges of the cylinder stand square up from the plate; when this is the case, finish the face by filing and scraping to the face-plate. File up also the edges of the valve-box which make the steam-tight joint, keeping the sides parallel by trying all round with callipers; scrape and finish these surfaces. File up also the oblong cover or lid on its flat sides, scraping up the inner surface to make a steam-tight joint. Lay the valve-box on the valve-face, in position, and the cover on that, and observe whether the outside edges correspond; if not, they must be made to do so by the file. It is not, however, advisable to file up the outside of the box, but only to make the edges come fairly even. The inside of the box should be filed out square and true, that its walls may form a

guide to the slide-valve. (See Fig. 7.) As they come from the foundry, the ports in the cylinder will not have their edges perfectly straight and square. Those who have studied the introduction to these papers will know how important it is that the exact dimensions here should be adhered to; it will not do to depart by even $\frac{1}{64}$ in. from the dimensions written on the ports and valve in Fig. 5. Take a piece of stiff card, the size of the valve-face of the cylinder, and draw upon it very accurately, with a hard and sharp pencil, the exact shape and position of the three ports from the views and dimensions given in Figs. 5 and 7; cut out the ports in the card with a penknife, and lay it upon the valve-face, so as most nearly to correspond with the three holes cast in it; take a sharp scriber point, mark off the holes on the iron, and file the edges of the ports to these marks. We will now proceed to screw the parts together. Eight long studs are required of $\frac{3}{16}$ in. diameter (screwed with $\frac{3}{16}$ in. Whitworth thread by preference), and these may be made from iron wire; the eight nuts should be of steel, and should be hardened. The washers are not necessary, though they look well. First mark out the positions of the eight holes on both sides of the valve-box, squaring across carefully from one side to the other; or, better still, take the card again, mark the holes on that, and then, after cutting out the holes, lay the card on the four surfaces and mark them with the scriber, taking care to keep the same side of the card always to the positions of the same studs: thus, the card might be laid first on the valve-face, and, after marking there the eight holes, then on the inside of the valve-face, then on the outer face of it, and lastly, on the cover. It is not at all an easy matter to get these holes exactly opposite, and great care must be exercised. How annoying it would be, let my readers imagine, to find, after screwing in the eight studs, that the valve-box could not be threaded over them. The amateur who can place his holes so correctly that the box will go on at the first trial may congratulate himself; if it will not, he will have to use a small "rat-tail" file in the holes through the sides of the box, filing away towards whichever side of the hole binds against the stud. So much then by way of frightening my readers into taking care at this point. Having marked, by means of the card template, all the eight holes as accurately as possible upon the four surfaces, drill the valve-box first from both sides with a $\frac{1}{8}$ in. drill, to meet in the middle; the drill will revolve in the lathe, and the work be pressed forward by the boring-flange, which should present it squarely and true to the drill. Watch the drill as it starts, to see that it does not "run" to one side at all, and you may hope the holes will meet fairly in so short a distance; if they do not perfectly meet, rub them out inside a little with a rat-tail file, used all round, equally, so as not to alter their position. Now take a $\frac{5}{32}$ in. drill, and put it straight through the holes from one side: $\frac{5}{32}$ in. is the tapping size for $\frac{3}{16}$ in., therefore it is the size to be used upon the cylinder-face. Choose any two of these holes, far apart, and drill and tap these first; they are already marked on the cylinder-face. Take their distance apart in the compasses, and try whether it corresponds with the distance apart of the corresponding holes in the valve-box. If it does, drill and tap them, keeping the tap very upright; screw in the long studs; enlarge the two corresponding holes in the valve-box to $\frac{3}{16}$ in. full; and put it on over these two studs. Leaving the cover for the present, screw on two nuts, and so fix the valve-box firmly up to the cylinder-face. Now take the cylinder as it is to the lathe, pass the $\frac{5}{32}$ in. drill through the six remaining holes, and drill into the cylinder-face; by this means the drill will be so guided that it will be, of necessity, both upright and in correct position. Take off valve-chest, enlarge the six $\frac{5}{32}$ in. holes to $\frac{3}{16}$ in., tap the six untapped holes in the cylinder-face, screw in the six remaining studs, and try on the valve-chest. You can easily bend the long studs a little if they are not perfectly upright, and the holes in the valve-box might be a trifle over $\frac{3}{16}$ in., say, $\frac{7}{32}$ in., allowing $\frac{1}{32}$ in. for clearance, errors, etc. The holes in the cover may be drilled $\frac{5}{32}$ in. first, and then it should be tried on the valve-box, when it will be seen whether they all come opposite; if any of them appear to be to one side, correct them with a rat-tail file, and then bore them all $\frac{7}{32}$ in., when it will go on. Mark the cover and the valve-box with the centre-punch, so that you may put the parts together always the same way. Now take all apart, except the studs, and slightly countersink the holes on both sides of the valve-box and cover, so

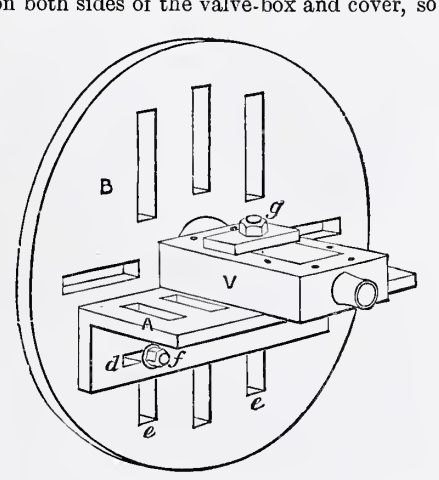

**Fig. 37.—Valve-Box chucked for turning Stuffing-Box.**

as to remove any rough edge that may have been raised up by the drilling, trying them on the surface-plate again to make sure the surfaces are still true. We will now turn our attention to the stuffing-box, which requires to be turned. To chuck this we shall require an angle-plate. An angle-plate is probably not often used by amateurs, but it is a very useful thing, and we shall want it again before we have done; it may cost to buy from five to six shillings, and is well worth the money. Fig. 37 shows how the valve-box, V, would be chucked upon the angle-plate, A; B is the face-plate, with its slots arranged rather differently to those in Fig. 36 (page 261); the parallel slots, *e*, *e*, are useful in connection with the long slot, *d*, in the angle-plate; two bolts, one of which is seen at *f*, pass through these slots, and thus the angle-plate can be moved in any position, up or down, by means of *e*, *e*, and sideways by means of *d*; this could not be managed by the radial slots shown at Fig. 36. The valve-box is secured upon the angle-plate by the bolt and oblong washer, *g*; and then the stuffing-box would be centred by moving the angle-plate on the face-plate, and fixed by *f* and its fellow, which is hidden. The two surfaces of the angle-plate must be strictly at right angles, and then the work done by its means will be true. The valve-box being fixed so that the stuffing-box is properly centred, $\frac{5}{8}$ in. from the inner face and $\frac{1}{2}$ in. from the other, start a $\frac{3}{16}$ in. drill very truly, and send it straight through the boss, to make a hole for the valve-rod; enlarge this with a $\frac{3}{8}$ in. drill for the gland to within $\frac{3}{16}$ in. of passing through; true out the hole with a slide-rest tool, and enlarge to $\frac{7}{16}$ in. Then screw it with the screwing lathe, or, failing that, use a gas-thread tap for "brass gas," $\frac{1}{2}$ in. diameter, and twenty-six threads to the inch: twenty threads would have been better, but twenty-six will do. The outside of the stuffing-box should be turned, and then the valve-box is finished.

*Slide-Valve and Rod.*—Take in hand next the casting of the slide-valve; file and scrape up the flat face, and then file the side edges square with the face, and parallel to each other, making the valve $1\frac{1}{2}$ in. wide, so that it will fit between the sides of the valve-box, as seen in Fig. 7. Now take the square and scriber, and draw four lines squarely across the face, and file to these, so as to make the flat edges $\frac{1}{2}$ in. wide, and the hollow space $1\frac{1}{8}$ in. wide, as shown in Fig. 5. The valve-rod is shown at Figs. 5 and 23; it might be turned down from a piece of round steel bar $\frac{9}{16}$ in. in diameter and $5\frac{1}{2}$ in. long. A piece of malleable cast iron is provided to make this rod. It must be turned down to $\frac{3}{16}$ in. and draw-filed, like the piston-rod, to prevent its wearing out the packing in its stuffing-box. A backstay will be required to support the rod against the lathe tool; a $\frac{3}{16}$ in. thread will be cut on the end of the rod for $2\frac{1}{4}$ in., and the four little nuts, for which castings are provided, would be chucked in a three-jaw chuck, which will hold them true by alternate sides. Then each nut would be drilled and partly tapped; then chucked on the tap while they are turned true (the tap being used as a mandrel) between the centres of the lathe. File the sides of the valve-rod joint flat, leaving a thickness of $\frac{1}{4}$ in. between two parallel planes, and bore a $\frac{1}{4}$ in. hole through for the pin, which hole must be strictly at right angles with the rod. The nuts upon the rod hold the valve between them—they are of brass, because otherwise they might rust fast to the rod; and they are in pairs, because then they can be locked together, turning one nut hard against its fellow, so as to prevent their working loose; besides, they enable us to adjust the position of the valve upon the rod, as we shall see further on.

*Screws for Cylinder Covers.* — At this stage, it may be well to fit the screws into the covers of the cylinder, and so complete that part of the engine. The screw-holes have already been bored in the two covers, six thoroughfare holes in each, $\frac{3}{16}$ in. full, to pass the six $\frac{3}{16}$ in. screws; place the bottom cover in position on the cylinder, taking care to put the two holes which are furthest apart opposite the port side; pass the scriber point through the holes in the cover, and mark their position on the flange of the cylinder. Drill these with a $\frac{5}{32}$ in. drill, and tap them with a $\frac{3}{16}$ in. thread. Make six screws of steel, $\frac{3}{16}$ in. diameter and $\frac{1}{2}$ in. long in the body, to secure this cover, and it would be well to harden their heads; make six more, $\frac{7}{8}$ in. long, for the top cover, since these have to go through three thicknesses of metal into the bed-plate. It is tedious, but very good practice, to file up the heads of these screws. The spanner would be made first to act as a gauge, then two opposite sides of the hexagon would be filed, holding the body of the screw in an universal chuck in the lathe, filing a little

off each side alternately till the spanners will just go on. The spanner, if correctly shaped, will show whether the sides are parallel; the four remaining sides are done by making the two consecutive ones of equal size, and trying as before with the spanner. The screws would be made of soft steel that will not harden of itself. Their heads would be heated in a blowpipe flame, then rolled in powdered prussiate of potash, again heated full red, and plunged in water, when they will have a hard skin without being brittle and liable to twist off. It is only the heads of the screws that require to be hardened, to prevent their being bruised by the spanner. It is not necessary to do it, but it is better, and they need not be cleaned up bright after the hardening, but only well oiled, as the blackened appearance looks well, and forms a contrast to the bright work. The bottom cover can now be put in. The top cover is secured in a different way, the screws going through the cylinder flange first, then through the cover, and finally screwing into the bed-plate. It is not quite orthodox to secure two joints with one set of screws, because one cannot be separated without the other, but it may do well enough on this occasion. Use the top cover, as before directed, to mark the screw-holes on the cylinder flange, but drill these holes $\frac{3}{16}$ in. full; and now we must lay aside the cylinder, and undertake the bed-plate

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

### 51.—Merrick's "Express" Gas-Heated Soldering Iron.

I have received from Mr. W. H. Merrick, 2, Summerfield Crescent, Birmingham, a specimen of his newly-invented "Express" Gas-Heated Soldering Iron. The appliance is in three parts, namely—a wooden handle, through which runs a tube, terminating at the lower end in a brass stop-cock, the end of which is shaped to receive an indiarubber tube communicating with the nearest gas-burner, the other end being screw-cut to take the lower end of the second part, through which runs a continuation of the pipe carried through the handle. This pipe terminates in a nozzle which enters the interior of the bit, which is hollow and pierced with two holes, by means of which the gas is ignited. The bit, which may be of any required shape, and which forms the third part, is about $1\frac{1}{2}$ inches in diameter at its widest part, and assumes a four-sided pyramidal form at its furthest end. The other end fits into a cup surrounding the gas-pipe that runs through it, and is held in place by a small set-screw. A portion of the cup is cut away at the shoulder to admit the atmospheric air. From this description readers will be able to form some idea of the construction of the iron. The following are the advantages claimed by Mr. Merrick for his gas-heated soldering iron over all others now in use:—1. It is constructed on a very light and compact principle, and is so made (as I have already explained) that the burner is inside the copper bit, thus doing away altogether with the outside arrangement of burners. 2. There is no stove required, thus doing away with the unhealthy fumes which rise from the coke stove. 3. The iron is ready for use in a few minutes after the gas is lighted, a very small supply of which keeps it up to the required heat, thus doing away with the use of extra irons, and the overheating and burning of the face, by which the face of the iron is always maintained in working order and never wears out, and a great amount of time and labour is saved. 4. By removing the reducing socket and replacing it by an elbow and tube, hatchet, glaziers, or pointed bits can be used interchangeably to suit any class of work. The use of this iron, Mr. Merrick urges, will be attended with great advantage in large factories where irons are constantly in use. Extra bits of any shape are supplied, and a price-list giving price of iron and bits will be sent by the inventor to any applicant. In the directions for use, instructions are given to light the gas at the "round hole marked 1," and this I take to be the upper and smaller of the two holes in the bit, as I can detect no mark on the bit before me. "If a still greater heat is required, the set-screw must be eased and the copper bit drawn out. To alter shape, remove socket and replace by elbow and tube. When in use the iron must not be raised to a vertical position." I have had the iron tried by a practical man, who tested it under various conditions; but he says that he finds a quantity of gas escapes unconsumed, and that there is a tendency to light back.

### 52.—"The Teacher's Handbook of Slöjd."

This is a handsome and well-illustrated volume of 216 pages, published by Messrs. George Philip & Son, 32, Fleet Street, London, E.C., under the auspices of the Slöjd Association. Its full title is "The Teacher's Handbook of Slöjd, as practised and taught at Nääs, containing Explanations and Details of each Exercise." The original Swedish work was written by Otto Salomon, Director of the Nääs Seminarium, assisted by Carl Nordendahl and Alfred Johansson, and it has been translated and adapted for English teachers by Mary R. Walker, St. George's Training College, Edinburgh, and William Nelson, of the Manchester Schools for the Deaf and Dumb. It is somewhat costly, its price being 6s.; but as it is intended for teachers and is not a text-book for use in schools, this will not militate against its sale and circulation. The first chapter deals with introductory remarks, showing what Slöjd is and the nature of the instruction to be given to the children, with remarks on the workroom, the position of the body during work, and hints and rules for the guidance of the teacher. The second chapter is devoted to an explanation of the structure and composition of wood, and the nature and characteristics of wood of different kinds. In the third chapter, the various tools in use and the manner of using them is explained, and instructions are given respecting the grinding and sharpening of tools. The fourth chapter is devoted to an exposition of the various modes of jointing; and the fifth chapter, to the exercises. The book is furnished with a good index; and at the end is given a price-list of tools and requisites as used in Sweden, and as supplied by Messrs. Philip & Son, who have been appointed agents for the Union of Slöjd Teachers in England, and from whom all the necessary tools, benches, diagrams, etc., can be obtained. The illustrations throughout the work are good; but special notice must be taken of, and special praise awarded to, the eight full-page engravings setting forth various positions to be assumed by the worker when engaged on different kinds of work. Such illustrations are always most helpful and valuable in the extreme to amateurs. The benches used are those known here and in Germany as German benches. They have an additional screw or bench vice at the end of the bench, to the desirability and utility of which English professional workmen are beginning to be alive.

Those who have not yet seen a bench of this construction should endeavour to have a look at one. It is by no means a difficult matter to do so, for many, if not most, tool-dealers on a large scale import these benches from the continent in different sizes and supply them to their customers.

The Editor.

## SUGGESTIONS FOR WORKERS AND HINTS TO INVENTORS.

Conjuring Tricks.—Few people, not professionally interested in such matters, know how valuable is any really good invention in the way of conjuring tricks, optical stage illusions, etc. Large sums have been realised by the inventors of the Flying Birdcage, Pepper's Ghost, "Magneta," "Thauma," "She," and other clever illusions which teach the public how easily the eye can be deceived under certain circumstances. The inventor of a really new illusion may feel secure of a more certain and prompt reward than usually follows the production of a most meritorious patent in another direction.

Etching on Glass.—Amateurs often inquire whether there is any simple process for etching on glass, and it happens that both French and German journals have recently devoted some attention to the subject. The German process is to mix common salt, carbonate of soda, and ammonium fluoride in equal proportions, which is placed in a gutta-percha vessel containing fuming hydrofluoric acid and concentrated sulphuric acid. A small quantity of potassium fluoride and hydrochloric acid are then mixed in a leaden vessel, and a little of this mixture is added to the former, with a small quantity of sodium, silicate, and ammonia. The composition thus formed can be applied to the glass by damping it with an indiarubber pad, or it can, of course, be used as an ink. The French recipe is far more simple. Dissolve 0·14 oz. sulphate of potash with 0·72 oz. fluoride of soda in half a pint of water. To another half-pint add 0·28 oz. chloride of zinc and 1·30 oz. hydrochloric acid. Mix the two solutions, and apply with a brush or pin. In about an hour after application the drawing or writing should be sufficiently etched.

Knife and Spoon.—A combined knife and fork has already been devised, but a knife which can at the same time be used as a spoon is yet to be brought out. The combination is by no means so difficult as it may seem, and once manufactured, it would meet with a certain amount of patronage for picnics, eating-houses, etc.

An Insulating Material.—Just at the moment the principal want in manufacturing circles is a good insulating material, air- and waterproof, non-inflammable, perfectly supple, and not too dear. In spite of all reports to the contrary, such a material has not yet been artificially produced, while gutta-percha and indiarubber are becoming more scarce and dear every year. It is worth trying to discover, as a fortune would await the discoverer or inventor.

A Much-Needed Invention.—Readers given to devising new apparatus, will be glad of a hint as to a profitable direction in which to employ their ingenuity. About five months ago, Captain de Place, a French gentleman, exhibited an invention called the Sciseophone in London, which, he claimed, would enable engineers to discover whether a piece of welded or cast iron or steel was free from flaws. As such an apparatus would be invaluable, if reliable in its results, the announcement of the trial attracted considerable attention. Unfortunately, it by no means justified the high expectations raised as to its success, and the world is still waiting for a flaw-detector that will enable the engineering world to be on its guard against defective axles, tires, etc. etc. The problem is not an easy one to solve, but electricity will, in all probability, be the main aid to its solution. It is most desirable that nothing be left to the judgment of the experimenter. No two people, for instance, attach exactly the same value to sounds, while the success of the Sciseophone depended chiefly upon the distinction between sounds of greater or less pitch. The results, moreover, should be self-recording. Very likely the Sciseophone indicates the direction of future success, but, as hitherto exhibited, it leaves so much to be desired as to justify anybody possessed of sufficient patience and ingenuity in devoting a large amount of trouble to the subject.

## SHOP:

### A Corner for Those who Want to Talk It.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### II.—Questions Answered by Editor and Staff.

**Removing Oil Marks.**—Anxious.—Repeated applications of oxalic acid dissolved in hot water (1 oz. to one pint of water) should effectually remove these from white holly or any other wood. Benzoline spirit will answer the same purpose, but must be used with caution, by keeping it a reasonable distance from naked lights.—Lifeboat.

**Phonograph.**—G. H. (*Camberwell*).—An article is in the Editor's hands upon this subject. Fittings cannot be bought at present.—W. D.

**Marine Engineer.**—Grafton.—In reply to the question of our correspondent, under the "Merchant Shipping Act Amendment Act, 1862," the certificates of steamship engineers are of two descriptions: viz., certificates of competency and certificates of service; and of each description of certificate there are two grades: viz., first-class engineers and second-class engineers. There is also the honorary certificate of "extra first-class." A second-class engineer must be twenty-one years of age. He must have served an apprenticeship to an engineer for three years at least, and prove that during the period of his apprenticeship he has been employed in the making or repairing of engines; or if he has not served an apprenticeship, he must prove that for not less than three years he has been employed as a journeyman mechanic in some factory or workshop on the making or repairing of engines. In either case he must also have served one year at sea in the engine-room as an engineer on regular watch in the foreign, home, or coasting trade, or he must have served at least four years at sea in the engine-room as an engineer on regular watch in the foreign, home, or coasting trade. When the workshop service has been performed in a place where steam-engines are not made, and the class of work done is similar to that required in engine-making, the service may be accepted with an additional year in the engine-room—that is, three years' workshop service and two years in the engine-room, of which one year must have been at sea. The approval of the Board of Trade must be obtained in every such case before the authority to receive a certificate is issued by the examiner. Service in a capacity below that of fourth engineer cannot be accepted as qualifying for any class of certificate, unless the testimonials of the candidate explicitly certify that during such service he has been taking regular watch in the engine-room, and that the chief engineer or superintending engineer considers him properly qualified by that experience to act as chief engineer of a foreign-going steamer of 99 horse-power nominal. In any case, the applicant must prove that he has had responsible charge of the engines or boilers for at least twelve months of sea service, of which for not less than six months he must have been in charge of the propelling engines, and rated on the articles not lower than fourth engineer. Service in the capacity of fireman, stoker, donkeyman, greaser, winchman, labourer, engineer's steward, or any other capacity than that of engineer taking watch on engines and boilers for propelling, will not be accepted. It is of the highest importance, now that such high pressures and seientifically constructed engines are used at sea, that there should be duly qualified and high-class steady mechanics to be entrusted with the charge of them, and for this purpose the Act was passed; and all engineers in charge of steamships must hold a first- or second-class certificate—either of competency or service—under a severe penalty both on the engineer and the captain who ships him. These certificates are obtained by an examination by a Board of Trade engineer, who, at certain appointed times, holds his examinations at different ports in the kingdom, when each candidate has to answer a set of appointed questions, and give satisfactory proof of his fitness to receive the certificate he seeks. If he fails, he is turned back, and he may meantime strengthen himself for those points where he was found deficient, and try again. If our correspondent thinks he would be able to meet the conditions laid down in the Act, he might apply to a superintending engineer or manager of a steamship company or owner to give him a chance of an engine-room job afloat. If he does not know any, let him get into a shop—such as Blair's—make up his mind to stick to it, get a good reputation for sobriety, steadiness, regularity, and perseverance, and he will soon get a chance in helping to erect or put engines into a boat, and then he may soon be able to get afloat. Let him spend his leisure in learning all he can relating to marine engines and steam, its nature, mode of action, and all relating to the care and management of marine engines and boilers, and try to get on, and he need not fear but his exertions will be attended with success.—C. E.

**Detective Camera.**—F. R. H. (*Rochdale*).—A full reply to your questions would occupy several pages of Work if it was to be of any practical value, and consequently out of the question to be replied to in these columns. Why not get some elementary work on photography, of which there are many published, and make yourself acquainted with the requirements of the art before attempting to make the apparatus to use in it? The knowledge of what you want will be of great assistance. We may suggest that Abney's "Modern Photography" is a very reliable work on the subject.—D.

**Pump.**—W. G. C. (*Sierra Leone*).—You can get such a double-action pump as you require of Hayward, Tyler & Co., 90, Whitecross Street, London; or of S. Owens & Co., Whitefriars Street, E.C., both makers of good repute. Write them, stating requirements, and ask for prices. You will find it cheaper to purchase one complete than to make portions yourself.—J.

**Delicate Machinery Oil.**—Oily.—Rangoon oil, mixed with a little paraffin, is about the best lubricant for gun locks, etc.—T. W.

**Vapour Bath.**—New Reader.—To answer your query fully would occupy too much space in "Shop." It will, therefore, be treated as a short article, and appear as soon as space will permit.—Ed.

**Field of a Griscom Electro-Motor.**—A. F. (*Clapham*).—I give an illustration of the field-magnets and pole-pieces of the Griscom electro-motor. The fields and pole-pieces form a closed ring of soft iron (as shown at Fig. 2). The semi-circular cores are wound with wire (as shown at Fig. 1) in such a manner as to form a south pole of one of the pole-pieces (P), and a north pole of the other. This is ensured by winding both in one direction. You will see that the armature is of the

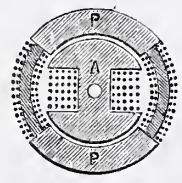

Fig. 1.

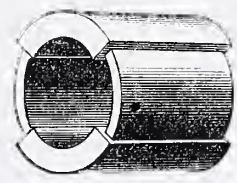

Fig. 2.

**Field of a Griscom Electro-Motor. Fig. 1.—Section through Field and Armature of a Griscom Electro-Motor—A, Armature; P, P, Pole-Pieces. Fig. 2.—Field of a Griscom Motor.**

solid H girder form. The ring should be 3 in. in length by 3 in. in diameter. The armature should be 3 in. in length by 1½ in. in diameter. Wind the armature with 3 oz. of No. 20 silk-covered copper wire, and the wire spaces on the fields with about 1 lb. of No. 18 silk-covered copper wire. If properly made and fitted, this motor will drive a sewing-machine when worked with current from six gallon size bichromate cells.—G. E. B.

**Moulding Plumbago.**—T. J. (*Somerset*).—Mix the finely-powdered plumbago with sufficient fine, well-washed clay to bind the material together without impairing its colour and polishing properties. Or you may well grind together two-thirds plumbago and one-third part of fire-clay until the whole has been reduced to a fine powder: then mould this, whilst wetted, with a solution of silicate of soda, commonly named water-glass. This composition will set very hard when dry, and stand almost any high temperature. If you write to Mr. T. Fletcher, gas-stove manufacturer, Warrington, I think he can supply you with prepared fire-clay for the purpose.—G. E. B.

**Composite Medical and Spark Coil.**—A. K. (*Aberdeen*).—In reply to your letter and questions: (1) It is not advisable to construct a spark coil according to the sketch sent by you, because this shows a coil more suitable for medical than for spark purposes. The sliding secondary, the draw tube, the brass regulator, and the break, are all unsuitable to a spark coil. You would only get a ⅛ in. spark from this coil even when worked with three pint bichromate cells. (2 and 3) Observe the same proportions as to length and diameter of core—viz., 6 in. by ½ in.; make the bobbin ends as shown in your sketch; leave out all arrangements for sliding the secondary coil; and, for a brass regulating tube, place the regulating screw for the break at the back instead of in front of the break-spring; wind on two layers of No. 20 silk-covered copper wire, well coated with paraffin, for the primary, and 8 oz. of No. 40 selected silk-covered copper wire, well coated with paraffin, for the secondary wire. With a condenser of fifty sheets of tinfoil (2½ in. by 2 in.) beneath the coil, and a current from two pint bichromate cells, you should now get a ⅜ in. spark, providing, of course, all parts have been well made and fitted, and the wire properly wound. (4) The coil cannot be employed to furnish current for driving a small motor to revolve the vacuum tubes. The current for driving the motor may be taken from the same battery as that employed to work the coil, but must be conveyed to the motor by a separate line of wire. The induced current from the coil above described will light up small vacuum tubes, but will not furnish current to revolve the tubes. (5) Composite coils are rarely satisfactory productions. They are like composite tools—inferior to those made for a given purpose. The beneficial uses of medical or shocking coils in the hands of amateurs are very doubtful. One may just as reasonably give children an unlimited supply of whisky to play with, as to play at giving shocks from a coil.—G. E. B.

**Moulding Compo.**—Sephton.—Moulding composition is prepared from French chalk and China clay; three parts of the former to one part of the latter makes a useful mixture when thoroughly kneaded with water to the consistence of stiff putty; but when the mess and labour of mixing are taken into account, I consider it cheaper to buy than to make in small quantities. This compo. is intended for use as detailed in the articles of Rubber Stamp Making; but if preferred, the dry materials may be mixed with an equal bulk of the finest plaster of Paris, and a sufficient quantity mixed with water immediately before the forme is moulded. —Qui Vive.

**Rounding Wood in Lathe.**—W. T. C. (*Derby*). —You will want a hollow mandrel with a chuck something like a pencil sharpener, except that the knife should not be arranged radially, as in the pencil sharpener, but the edge must slant somewhat spirally, so as not to tear up the fibres of the wood: only a slight obliquity will be sufficient to give a *slicing* cut. With this you can push in the squared wood, and have it come out round. The knife must, of course, be adjustable, and removable for sharpening.—F. A. M.

**Soap.**—Basso Profundo.—Very good soap can be made with olive-oil alone. The time during which the alkali will keep warm varies with the temperature of the surrounding air and the quantity of solution in question, but the solution may be re-warmed, if necessary, without injury. I have never observed any injurious result from the action of the caustic soda solution on either tinware or soldered joints.—Herbert Clark.

**Type.**—A. B. & Co. (*Belfast*).—Metal-bodied rubber types are imported by M. Lindner, 170, Fleet Street, London, E.C.—Qui Vive.

**Type.**—A. J. H. (*Hulme*).—Is there not some error in your description of the transfer process to which you allude? The final result of the process as described by you would be a *reverse* impression identical in appearance with that of ordinary type viewed direct. Are the figures transferred to the *back* of a *transparent* dial?—Qui Vive.

**Clock Bracket.**—F. H. M. (*Manchester*).—There is a design of a very pretty bracket for a clock in Vol. I. of Work, which might meet with your taste. The index says, "Clock Case and Brackets," pages 241 and 264. If it does not suit you, however, place your query in our hands again. Refer to Indexes of Vols. I. and II. for brackets in fretwork, suitable for the same requirements. Have you examined all the fretwork designs in the available catalogues of the various firms advertised from time to time in this Magazine? If not, do so.—J. S.

**Carpenter's Bench.**—J. O. H. (*Wandsworth Common*).—Many allusions to carpenters' benches have been made in Vols. I. and II. of Work. Refer to the Indexes. This subject is one which cannot be conveniently dealt with in the confined space of "Shop." Continue clamouring, ye carpenters, and if much demand is exhibited, rest assured our Editor will, as soon as possible, find a corner for the above article. I have retained your address privately, and if you will enclose the necessary stamps to the Editor, with query repeated, I will forward you the address of a professional bench maker who supplies "Curtain-Road" men. It would be out of place to print it here.—J. S.

**Camera.**—J. T. (*Rawtenstall*).—In the first volume of Work will be found instructions and working drawings for making a camera according to the plan of George Hare, of 26, Calthorpe Street, London: a design that has been, more or less, adopted by many camera makers of repute as a convenient and thoroughly useful pattern, and up to the present time no better is in the market. Most of the material and brass work for constructing one may be purchased at H. Park's, 1, Orchard Buildings, Acton Street, Kingsland Road, London, N. With regard to coupons, we will give them our consideration. Any special form of apparatus sold by one firm only had better be procured for a pattern, as it is impossible for us to assist you in this matter and these columns otherwise than in a general way.—D.

**Banjo.**—Banjo Slogger.—If your banjo wants improving in tone, you will not be able to improve it by fixing a sounding-bell to it. There is a banjo made in London with a piece of metal across the inside of hoop very similar in appearance to a shallow dish, with a large hole in the centre. The edges of metal lay on the top edge of hoop underneath the vellum. I suppose it is a matter of taste, but to my mind this is not an improvement, as far as tone is concerned. Of course, the opinions of various individuals differ in regard to banjo matters as they do to various other things; we cannot all think alike. This banjo is patented, so you would not be able to make it. There is a banjo known as Dobson's bell model. The top edge of metal hoop is not spun over a wire, but is bent over in the shape of half a circle, about ¾ in. in diameter, from which the banjo takes its name of bell model. The tone of this is very poor; instead of being an improvement it is just the opposite. Then

there are banjos with metal backs to them, double rims, solid metal rims, and a host of other so-called improvements; but I have yet to see the *improved* banjo that will *equal* one with German silver hoop, edges of hoop spun over steel wires, the vellum put on properly, and everything about it being well made. There has been a great number of so-called improvements made in connection with the violin, but they soon die a natural death; and I think it will be so with the banjo: the double-spun-edge hoop will hold its own against all comers. You should look up your back numbers of WORK, and read my replies to correspondents. If your banjo can be improved, you will there find all the information you require. Please understand that I write this as my own individual opinion. I do not pretend to be infallible. If at any time I am wrong, I am always open to be corrected.—J. G. W.

**Electric Light Materials.**—NOVICE.—What power is driving your belt-wheel? Much will depend upon your reply to this question. Supposing you had a small machine with a driving pulley on it 1 in. in diameter. This, when driven from a wheel 1 ft. in diameter making 90 revolutions per minute, will only develop a speed of 1,080 revolutions per minute. As small electric light machines require to be driven at a speed of 3,000 revolutions per minute, you would not be able to drive the machine fast enough to get any light from it. It is possible to make a large machine to be driven at a very slow speed, but the cost would be something considerable.—G. E. B.

**Water Motor.**—M. G. H. (*Smethwick*).—Your 12 in. circular saw may be driven by your water motor in cutting soft wood up to 3 in. deep, and to greater advantage than if driven by hand. Any power that may be devised and maintained is far better than hand power, as it is impossible for a man to drive a circular saw by hand, even for a short time, near its standard speed. I cannot see that your suggestion in reference to pumping the waste water into the upper tank would be advisable. It will require all the power to drive the saw, and if the water was pumped up into the tank by the same motor while the saw is at work, the power required to drive the saw would be so diminished that it would be a failure. No power is so economical as water power. If you can so fix your motor as to have a regular stream of water equal to the power stated, you may drive your saw to advantage. As to a windmill to raise the water to the top tank, unless there is a certain pressure of wind it is impossible to raise the water; and should there be enough wind to drive the mill, it may stop at any moment, when the whole concern will come to a standstill: therefore I can say nothing in support of it.—A. R.

**Engines.**—A. T. (*Dublin*).—I replied to this question, or to one identical with it, some time since, saying that such engines could not be described properly except in a short series of articles.—J.

**Workshop Agreement.**—AN AMATEUR MECHANIC.—We do not undertake to answer legal questions.

**Papier-Mâché.**—GOOD IRON.—There are articles on Papier-Mâché in Vol. I., pp. 33, 87, 182, 265, 348, 387 (Nos. 3, 6, 12, 17, 22, 25); and in that and Vol. II. are also many answers on points connected with it in the "Shop" column.—S. W.

**Photography.**—J. M. (*Kilmarnock*).—(1) You can obtain the tools you require at many cutlers. Buck, of Tottenham Court Road, and Moseley, of New Oxford Street, supply them. (2) Coat the block with a mixture of twenty grains of chloride of ammonium, five grains of gelatine, and thirty grains of zinc oxide to one ounce of water. Let this be brushed equally over the surface, and dry. To sensitise it, brush over it a solution consisting of ninety grains of silver nitrate and five grains of citric acid in one ounce of water; dry, and print under a negative in the usual manner. Wash the surface with warm water, and fix with a solution of hyposulphite of soda, one part in four of water. Wash again, and dry carefully in a cool current of air, the block standing on its side. The application of moisture must be confined as much as possible to the surface, to avoid warping the wood. On no account attempt to dry by artificial heat, as over a stove or before a fire. The block must be allowed to dry spontaneously, as any curvature of the surface will totally unfit it for printing purposes.—D.

**Steamboat.**—O. M. (*Barrow-in-Furness*).—I presume you want to make a copper hull for your model steamboat, but imagining, from the tone of your letter, that you know very little about sheet-metal working, I should advise you, if you want a nice job made of it, to place the order in the hands of a competent coppersmith. I can recommend Stevens & Son, Whitecross Place, Wilson Street, Finsbury Pavement, London, who have given me the greatest satisfaction in sheet copper work, and at a very reasonable figure. Instructions for doing this are somewhat difficult to put on paper, but after cutting your plates roughly to size, they will have to be shaped by hammering on a suitable "stake," using a hammer with a slightly rounded fall. This causes the copper to expand at the point struck, and thus by judicious hammering on either side, according to shape required, the plates can be given the necessary curvature. Half an hour's practical illustration will do more good than a whole page of written instructions. You will want a deal of practice before you will be able to turn out a good job; but before you commence in earnest, practise on a few waste pieces. You will also do well to look up "Hints on Hollow Work in Sheet Metal" on page 282, No. 18, Vol. I. There were also, I believe, some articles on Sheet Metal Working in Vol. II., but as I have not my copy by me at present, I cannot give you the Nos. of the parts containing them.—H. E.

**Wood Engraving.**—T. M. (*Kilmarnock, N.B.*).—A wood engraver in London capable of producing work similar to that of the proof sent by T. M. would command about 10d. per hour. Of course, the time he mentions—seventy-five hours—would be considered extreme, as division of labour is carried out to great advantage here. We should not think of employing one man only to carry out the three operations of photographing, drawing, and engraving. A professional would take the original photograph: that would be passed on to a photographer on wood; a mechanical draughtsman would do the necessary working-up of same before it was passed on to the machine-ruler, who would engrave all tints and cylinders, leaving the engraver to "back up" tints and finish up all details.—T. P. C.

**Ebony Stain.**—A. C. (*Leicester*).—If only a small quantity is required, it will be better to buy the French black stain, as sold at most places where veneers are sold, at about 1s. per pint—sufficient to stain about eight square yards. I have had some very good from Kingston, Veneer Merchant, Pershore Street, Birmingham; but as the question is frequently asked how to make these stains, I append a few recipes, a glance at the composition of which will show you what is meant by saying it is cheaper to buy small quantities ready-made; besides, in the majority of recipes two distinct operations are required, using different substances, whereas in the French stain one application will give a satisfactory result; subsequent coats will increase the intensity of the blackness. You only ask for a dull black stain. I presume you can polish; if not, my advice is, don't take your first lessons on black work, or you may finish up by saying it's a failure. If, on the other hand, you have a fair insight into the art of polishing, it may be well to remind you to use a little vegetable or common black mixed with your "filling in," and a little ivory drop black, or Frankfort black, mixed in your polish, which latter should be what is called white or transparent: not the brown, as made from common shellac. Ebony stains:—(1) 2 oz. logwood chips, 1½ oz. copperas, one quart of water. Apply hot, giving several applications; then one or more coats of vinegar in which has been steeped 2 oz. steel filings to the half-pint of vinegar. (2) one gallon vinegar, 2 lbs. extract of logwood, ½ lb. green copperas, ¼ lb. China blue, 2 oz. nut-galls; boil in an open pot till dissolved, then add half-pint of iron solution, made by steel filings and vinegar, as in No. 1. (3) 1¼ oz. gall apple, 3½ oz. logwood extract, 2 oz. vitriol, 2 oz. verdigris, one gallon water, half-pint iron solution. (4) ½ lb. of logwood, three quarts of water, one handful of walnut peelings; boil for about three hours, then add one pint of boiling vinegar. Give several applications of this, allowing each coat to nearly dry before the next is applied; then give one or more coats of copperas solution—half-pint of copperas dissolved in one pint of water. It will be noticed that for the iron solutions steel filings are advised. Should any difficulty be experienced in getting these, old rusty nails—a handful to the pint of vinegar—will do.—LIFEBOAT.

**Combe Down Stone.**—E. L. (*Bath*).—I am obliged by your note referring to the omission of the mention of Combe Down Stone in the list of Bath stones in my article on Masons' Work on page 99. When I wrote the article I was quite aware of the name and qualities of the stone; but from information I had received some years ago, I was under the impression that very little, if any, of this stone could now be produced; and although I made inquiries, I could not hear of any firm which supplied it, and therefore omitted mentioning it. I am now, however, informed that it is supplied by Mr. Edwin Love, Odd Down, Bath. I have also been informed that there is another stone, named Monk's Park (not named by me), which is of similar quality to Corsham Down, and also that Bath stones are supplied by other firms than those named.—MUNIO.

**Materials for Painting on Pottery.**—NOVICE will, doubtless, be able to get what he wants by post from Brodie & Middleton, Long Acre, London, W.C.; or probably from Lechertier, Barbe & Co., Regent Quadrant, London, W.C.—S. W.

**Calcined Bones.**—RAYNOR.—The required article is, we believe, used in china-making, and could doubtless be got at china works; but surely, as so small a quantity is needed, it might more readily be made at home. There can be no difficulty in burning a few bones in the grate, pounding, and sifting through a piece of muslin to ensure the required fineness.—M. M.

**Oil Canvas.**—J. M. (*Grangetown*).—It would be much better to buy the canvas prepared, as you never would be able to prepare it so well. It is not expensive, as you can buy a canvas already fixed on stretcher for use—15 in. by 12 in.—for a shilling. However, should you not be able to get it, and so have to prepare it, you must get some white-lead, make it up with boiled linseed oil and a little patent driers, and cover the canvas evenly over, and as thick as possible. Let the colour be as round as you can get it on. Let it thoroughly dry, then paper it smoothly. Give it another coat of colour, with a little thinning of turps in it, and stain it with a little umber, making it a very pale stone colour—it is better to work on than white.—W. C.

**Saws and Lathes.**—A. C. (*No Address*).—By the time this meets your gaze, information in reference to saw hammering, fully answering your question, should appear in WORK. Lathes for the work you mention may be had from Thomas Robinson & Co., Rochdale, and from A. Ransome & Co., Chelsea, or from almost any maker of wood-working machinery. There is an automatic lathe made by an Ohio Company, for whom J. Sagar & Co., Halifax, England, are agents. This machine, I hear, will turn out 1,000 spokes per day. But as you want a cheap machine, I am afraid these will be too expensive for you; but you will find all cheap machines dear in the long run. I saw recently a rough-made copying lathe made by a maker of Exeter, whose address I have not to hand; price £15. It must be understood that the work when taken from these machines is not ready for painting; a buffing machine is required to remove the ridges caused by the cutters. The machine consists of two endless belts (or even one will do), covered with ground glass, which run at a very high speed over pulleys. The article, after being turned, is pressed tightly on the belt by hand, and the ridges left by the cutters removed. A machine with two belts will clean up from fifty to sixty spokes per minute. The first-named makers make a machine called the "Wheelwright," which will plane boards up to 13 in., and will square and joint scantlings up to 12 in. by 9 in.; also face up felloes; it will plane shafts and poles to any template; will mortise naves up to 14 in.; cut grooves from ¼ in. to 1½ in.; tang spokes of wheels up to 6 ft. diameter after driven in stock; mould, bead, and rebate, and bore holes up to 6 in. deep up to 2½ in. diameter. It is claimed to do the work of at least twenty men.—A. R.

**Soap Making.**—S. (*Derbyshire*).—The water used for dissolving the alkali need not be boiled. Clean cold water is all that is required, but this will become very hot as the alkali dissolves.—HERBERT CLARK.

**Soap.**—BARBER.—I exceedingly regret that I am unable to give a satisfactory reply to your query as to shaving soap. Whether or not a lather made from the soap described in my article on Domestic Soap Making would "creep" I am unable to say, but I can safely assert that it will not irritate the skin if properly made according to my directions. A small proportion—say, one-eighth—of pearlash to the alkali would make the soap lather better, but I do not know whether or not the soap so formed would be too irritating for your use.—HERBERT CLARK.

**Meaning of Voltage and E.M.F.**—OBLONG.—E.M.F. are the three letters commencing the three words Electro-Motive Force, and are used instead of these three words to save time and space. This term means the pushing force or pressure of an electric current as expressed in *volts*, and this leads to the use of the other term "voltage," which is sometimes employed instead of the three letters E.M.F.—G. E. B.

**Keeping Rubber Soft.**—J. G. (*Rochdale*).—I know of no reliable means whereby rubber may be kept soft, as the softness depends very much on its purity and amount of exposure to atmospheric influences. Even pure rubber hardens on exposure to the air for some time, especially in cold weather, and much of the so-called rubber becomes quite brittle under such circumstances. The better descriptions of rubber, whether raw or vulcanised, may be considerably softened by being well kneaded at a temperature of eighty or ninety degrees Fahrenheit. Rubber articles retain their softness and pliability best when kept in use; and when out of use, preserved as much as possible from exposure to the air.—QUI VIVE.

**Soldering Jewellery.**—T. N. (*Halifax*).—This gentleman must dismiss from his mind all previous ideas that soldering means the use of lead or pewter solders. Soldering, when spoken of by jewellers or silversmiths, means the melting by heat of an alloy of gold or silver, such alloy being specially prepared for different qualities of gold or silver, and in many cases from the gold actually being used to make the article. The principle that governs the making of the solder is that the better the quality of the gold or silver the greater the heat that is required to melt it; and conversely, the lower the quality the easier it is to melt. For example, a writer gives the melting point of 18 carat gold at 1995 Fahrenheit, of 15 carat at 1992, and 9 carat, 1979, while easy silver solder melts at about 1802 Fahrenheit. This, I think, makes clear that, although one could use 9 or 15 carat gold to solder 18 carat, it is not possible to use 18 carat to solder 15 carat. The same principle applies to silver and brass: and the quality of the solder has to be known before any attempt should be made to carry out the actual soldering of an article. Another important matter to bear in mind is that thin gold articles, like brooches, will not bear so hard a solder as the same quality of gold will do when made up solid, as in the case of a bangle ring. Solder for 18 carat and 15 carat: take 1 dwt. of the gold, and add 2 grs. fine silver and 1 gr. fine copper; melt well together, and flat to size 6 or 7 Shakespeare gauge. For 12 carat, the addition of 3 grs. fine silver and 1 of fine copper to the dwt. is advisable; while for 9 carat the most useful solder is made from 1 part fine gold, 1 part fine copper, and 2 parts fine silver. For silver, a hard solder can be made by adding to 5 dwt. fine silver, 1 dwt. 8 grs. fine copper and 8 grs. of spelter; or else to

the 5 dwt. of silver, add 1 dwt. 16 grs. of good quality brass wire or pins. These and the next alloy have a volatile metal—viz., zinc—and must have the silver melted first before the brass is put in, plenty of borax being used all through the operation. For easy silver solder, take 10 dwt. fine silver and 5 dwt. brass wire or pins, and melt and flat to size 6 or 7. For solder easier still, use spelter in place of brass wire. All these solders can be bought at any refiner's or jewellers' material shops, of which there are plenty in Birmingham and London. Once the proper solder is obtained, it is easy to do the actual soldering of plain, solid articles. All that is required is that the parts to be joined are held firmly in contact, iron wire being the usual means. These contact surfaces are scraped perfectly clean, all hurr being removed as well. Next charge the join with a paste made from lump borax rubbed up with water on a piece of clean slate. This paste is used of a milk-like consistency for gold solders, but for silver soldering it should be quite as thick as cream. Next charge the seam with pallions of solder, and blow a jet of flame from gas or spirit on to it until the solder runs. The heat should be applied gently at first, for the horax will swell up, and is likely to move the pallions of solder away from the places they are meant to remain in until flushed. Pallions of solder is a name given to the square or oblong pieces produced by cutting a piece of flat solder into a row of parallel teeth, then by cutting again direct across these; their size heing larger or smaller, according to the work in hand. Better that three or four small pieces be put on the work than one large one. The solder should be scraped before being ent, for on the perfect cleanliness of all the details the success of the soldering will now depend—that is, if the heat is correctly applied. And one fact to remember is that solder will run towards the place where the greatest heat is. I hardly know where to leave off, for soldering —a very simple process in itself—becomes a most difficult art to practise with success in the numerous and varied conditions of jewellery making and repairing. This, however, it will be well to hear in mind: no lead or pewter must be in work that is to be hard-soldered, else the portion covered hy it will he destroyed. Look up in Vol. I., No. 14, p. 220; No. 19, p. 301; No. 38, p. 588; No. 46, p. 732; and in Vol. II., No. 76, p. 388; No. 104, p. 828, for replies bearing on soldering and jewellery repairing.—H. S. G.

**Brazing.**—A. E. (*Blackburn*).—You would have done well to have specified the particular kind of work or material that you wish to braze. The information then would be more likely to be of service to you; as it is, I can only answer you in a general way. Brazing is a method of uniting metals with a material called spelter, also called hard solder, to distinguish it from soft or tinman's solder. Requiring, as it does, a far greater degree of heat to melt it, the ordinary means used for soldering are of no use in this case. We must, therefore, look for some means whereby a great heat can conveniently and quickly be applied to the work. These means are found in the forge, the aëro-hydrogen blowpipe, and the self-acting blowpipe. The first named you are, no doubt, familiar with; the second is a means of producing a very powerful heat by means of ordinary hydrogen or coal-gas mixed with air under pressure. If you will write to Messrs. T. Fletcher & Co., gas engineers, Thynne Street, Warrington, for a list of their gas appliances for the workshop and laboratory, you will there find several of these blowpipes illustrated and explained. The third has been fully described in various Nos. of WORK (consult Index to Vol. I.), and need not be enlarged upon again here; suffice it to say that they are only suitahle for small work, such as key-brazing, etc. The mode of preparing the work is varied, but in this, as in all other ways of uniting metal, the parts must be elean and free from grease. They must also he well fitted. Say, for example, you wish to braze a bicycle neck into the backbone. It is of the greatest importance to get a good fit. I remember a querist asking how much room he should leave for the spelter to run in. If any such thought as that is in your mind, I say none at all. Fit them together as neatly, as elosely, and as firmly as if there were nothing else to be done to it. Next make a strong clear fire of small coke, and while the hoy is blowing this clear, powder up some borax. Take a teaspoonful of this, and mix with a teaspoonful of spelter, and make it into a paste with a little water. You will also require, to put this paste on to the work, a small tool called a spatula; it is simply a piece of ¼ in. rod flattened out about the size and shape of a small mustard-spoon, and about 18 in. long. Having got the fire perfectly clear and free from smoke, place the work upon it for half a minute to get warm; then with the spatula pack round it some of the paste of spelter and horax; have close at hand some powdered borax without spelter. Now replace the work on the fire, and blow steadily, gradually increasing the pressure. At first the mixture will rise off the work as the heat is applied; it must then be pressed down with the spatula. This must always be dipped in cold water every time it is applied to the work, or it will drag the spelter off. As the heat increases, sprinkle some powdered borax on the work as it commences to run, add more spelter, and rub round with the spatula, keeping up a gentle blast till you see that the metal has run well in all round. Remove gently from the fire, and stand it hy to cool gradually. I have not space to go into particulars as to brazing copper and brass, except to say that greater care is required, and spelter of a quicker fusibility than is required for iron. If you require more information, write again; we are always willing to help you.—R. A.

**Wiped Joint.**—BLOWPIPE.—A wiped joint is prepared in the same way as for a hlowpipe or copper hit joint, as far as fitting and cleaning are concerned, but after that it is very different. (See Fig. 1, which represents two pipes fitted together.) The parts shaded are coated with a composition of lampblack and weak glue water, and a little stale heer or a little sugar. This is called "soil" or "smudge," and its object is to prevent the melted solder from adhering to the pipe where not required. The parts from A to B are scraped clean and ruhhed with "touch" (tallow); the metal is then applied to the joint, either by splashing it on from a ladle with a splash stick, or hy pouring over it with a small ladle metal dipped out of the metal pot, or by using sticks of solder and a hlowlamp such as the Paquelin, which is very useful indeed for these joints, as the iron can he dispensed with. The metal is then wiped round to the proper shape (shown hy the dotted lines). To do this, proper wiping cloths

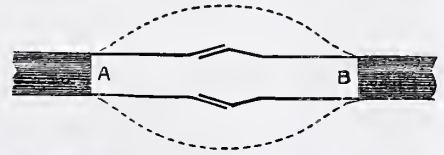

Fig. 1.

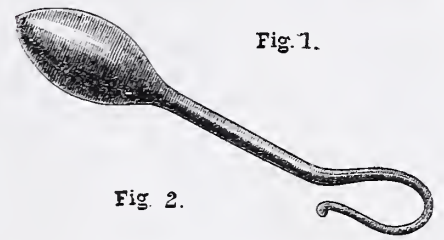

Fig. 2.

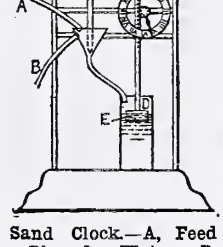
Fig. 1.—Plumbers' Joint. Fig. 2.—Iron.

must be used; they are made of several thicknesses of fustian or ticking stitched together, and should be well ruhhed with tallow before using. Various sized cloths are required, from 2 in. square up to 5 or 6 in., according to the size of the work. The metal must be kept at just such a heat with either blowlamp or iron (Fig. 2) that is soft and plastic, but not liquid enough to run. Burnt fingers are usually the result of first attempts, hut once the knack is attained it is easy enough—that is, simple joints such as you speak of. Proper plumhers' solder must be used.—R. A.

**Sand Clock.**—H. K. D. (*No Address*).—I have never seen a sand clock, and, I should think, it would be too bulky if you made one to go even thirty hours; hut you could make a simple one, no douht—say a tnhe of wood three sides, the fourth side of glass. Make a metal funnel with a small hole, and fix at the bottom, and have a box underneath to catch the sand. Fill your tube with dry sand, and having pasted a strip of paper outside on the glass, mark the hours, as the sand is falling, with your watch or clock. The tube could easily he fixed to the wall, and hy experimenting you would be able to find the length and size of tube and hole in funnel at bottom, where it has nearly run out. Pick up the box and refill the tube; but I am afraid your tube would have to be large and long to get it to run even twelve hours without attention. You might use water instead of sand; let it drop in a glass vessel, with a paper with the hours pasted on its outside; or let it raise a float—say, a large cork with a wooden or metal upright fixed to it. On the upper part it can have teeth working in a wheel that shall have a hand fixed to it, and so revolve as the water rises, and show the hours. This is an old Egyptian style of clock, in use about 200 years B.C. This sketch may suit you; it explains itself.—A. B. C.



Sand Clock.—A, Feed Pipe for Water; B, Overflow; C, Conical Stopper to regulate Flow into the Cistern; D, Cistern; E, Float with Arm to work the Wheel carrying Hand.

**Colouring House.**—H. L. (*Higher Bebington*).—I am glad to find that your incuhator promises so well, and hope you will derive great pleasure and profit from its use. With regard to colouring "the apiary," any colour can be ohtained by first preparing a wash of whiting or lime as for ordinary whitewashing, and then mixing in colouring matter until the desired tint is ohtained. For *pink*, use rose-pink; for *salmon*, Venetian red; for *lilac*, a little indigo and rose-pink; for *grey*, lamp-black; for *French grey*, Prussian blue and lake; for *blue*, Prussian hlue, indigo, or cobalt; for *green*, emerald green; for *buff*, yellow ochre; for *drab*, burnt or raw umher. To fix the colours, size should be used. I would advise you to mix a small qnantity at first, and apply it to a patch of the hack of the house. When it is dry, an estimate can be made of the effect. These colours usually dry lighter. I would advise you to get *Every Man his Own Mechanic*, which contains a world of useful information.—APIS.

**Chemicals.**—W. W. (*Chelsea*).—You can get the chemicals you require of Burgoyne, Burbidges & Co., 16, Coleman Street, E.C.; Townson and Mercer, Bishopsgate Street Within; or Orme & Co., 65, Barbican. The prices vary a lttle, bnt are about as follows:—Ferric oxalate, 1s. per oz.; ferric oxide, 8d. per lh.; ammonium oxalate, 3d. per oz.; hydrated peroxide of iron, 1s. per lh.; perchloride of iron, 9d. per lb.; protochloride of iron, 1s. 6d. per lb.; potassium ferrocyanide, common, 1s.; pure, 2s. 6d. per lb.; and potassium ferricyanide, common, 2s. 4d.; pure, 5s. per lh. These last two salts vary a good deal in price, different chemists charging differently according to which manufacturer they obtain it from. Oxide of iron is the same as ferric oxide, and chloride of iron as perchloride of iron. Ammonio-citrate of iron is *not* the same as peroxide of iron, it heing a compound, consisting of ammonia, citric acid, and iron, whereas peroxide of iron consists of iron and oxygen. I do not know the price of it, but you can get it from the above firms.—F. B. C.

**Penholder.**—J. W. H. (*Chesterfield*).—The two samples sent are for an apparatus and arrangement to be applied to a particular purpose. Now, as the *second* consists of precisely identical parts, acting in an identically similar manner, and producing precisely similar effects, there is consequently no novelty in the *second* arrangement, for which any exclusive legal right could he ohtained, nor which the law could support, as it would fail in not possessing the novelty required by law to make it a valid grant. If the *second* arrangement were manufactured and put on the market, the owner of the *first* could institute proceedings for infringement, and would, if the invention were novel, and his claims, title, and specification properly drawn, so that the law could support his right, be sure to win, with damages for the infringement of his exclusive rights by the *second* party. The use of the spring seems to he the only novelty, hut to use the plan the *second* would have to obtain a licence from the *first*, always supposing that the first possesses a legal right to the invention.—C. E.

**Thicknessing Gauge.**—J. A. (*Peterhead*).—The gauge shown on page 85, No. 110 of WORK. is not on sale, hut if you write me, through the Editor, I will make one for you.—B.

**Violin Bass Bar.**—B. F. E. (*Carlisle*).—To show you that the bar performs both functions, you need only string up to concert-pitch an otherwise properly constructed instrument, *minus the bass bar*. The pressure will cause the inner side of the bass sound-hole to become depressed helow its normal position, and as this is not the case when the bar is in position, correct in size, etc., it is evident that it has a "mechanical" function: viz., to support the helly. The paucity of penetration and the decidedly nasal quality of tone will convince you that it has also an "acoustic" function. In both letters you state that you have formed a theory, after many years of study, as to the construction of the bar, and wish to know whether or not it is erroneous. How can I express an opinion without first knowing what your theory is? I imagine that a person who entertains a theory, and, putting the theory to a practical test, finds the result precisely that which he anticipated it would be, may fairly claim that the theory is correct. You say, in regard to the sound-post, that you found the best place for it, and left it there, but I do not gather from your letter that you worked out the *reason why* it was the best. Should you encounter any difficulty regarding the practical part of fiddle building, I will do my best to assist you; but I cannot undertake a correspondence the end of which cannot be foreseen respecting the theories of either one or another.—B.

**Decanter Stains.**—CONSTANT READER.—To remove old stains from decanters, several different articles may be used, such as egg-shells, shot, coke; but what perhaps answers better than anything else are small pieces of coal. Put some into the bottle, and shake well for some little time, when I think you will find it will be perfectly cleaned. What was used to dry the bottle in the case you mention I do not know; but if heat is too slow a process, methylated spirits of wine will almost immediately evaporate the moisture from anything. Whether you would care to use it in the case you mention, I must leave you to decide.—W. E. D., JR.

**Slide Rule.**—A. (*Preston*).—Slide rules are of several different kinds, and may be ohtained at most mathematical instrument makers. We do not know who makes the rule our correspondent refers to, though we recollect some twenty-five years ago the person named having shown us some made in wood. Routledge's slide rule seems as good as any for ordinary all-round work; but we should advise our correspondent next time he is in Liverpool just to look in at the mathematical instrument makers, and see if he cannot find amongst the different kinds something approaching what he requires. He might also see what he can find at the engineers' tool makers either at Preston, Liverpool, or Manchester.—C. E.

**Scrap Tin.**—Tin.—Do you mean the cuttings such as are made by tinplate workers in the manufacture of goods, or do you really mean scrap tin, which I should understand to be scraps and oddments of the pure metal? If it is the latter, your possession of "some tons" of it is indeed a valuable one, as the price quoted for English ingot tin last month was £94 10s. per ton; and if you have several tons of this, it would be the best plan to send it to a metal merchant as it is. They could run it down cheaper than you could, and they would give you a fair price for it. Even if you went to the expense of running it into ingots, it is very doubtful whether you would find a sale for it at anything like tin price, as it would have no brand of guarantee upon it. All Cornish ingots have the mark of the Duchy of Cornwall on them—the lamb and flag. Now for the other case. If your treasure is only tin cuttings—that is, iron coated with tin—it is, comparatively speaking, of very little value, and you can soon calculate whether it will pay you to try and re-cover the tin. I estimate that you might get 2 lbs. of tin per cwt. of scrap. This would be 40 lbs. per ton; more likely less than more. The utmost value of this would be 35s., so that you might expect from four tons about £7. Deduct from this, say, 25s. for fuel, and take your time into account, and you will see that it is not a very profitable speculation, and that it would not be a very wise thing to buy bellows, or such like expensive appliances, to melt it down. I know it has been tried, but I think the only people who make it pay are the gipsies. They build up a big wood fire (which costs them nothing), throw a heap of cuttings and old kitchen utensils upon it, set it alight, and let the metal run on the ground, and when cold, dispose of it at the nearest marine store dealer's. If you treat your scrap in a similar way, it may pay you—that is, if your time is not of much value; but if it is, my advice is, have nothing to do with it.—R. A.

**Camera.**—A. W. (*Paisley*).—So far as we can make out by your post-card, there is nothing particularly new in the design; revolving backs have been some time in the market. You do not say what the intended improvement is to effect, or what mechanical movements are to be superseded. The diagrams are not sufficiently clear to enable us to form an opinion. Under any circumstances, we should hesitate to recommend taking out a patent. —D.

**Back Parts of Work.**—A Lover of "Work."—You can get any back monthly part or weekly number of Work by ordering it through your bookseller or newsagent. Failing him, write to the publishers, Messrs. Cassell & Company, London, E.C.

**Wardrobe.**—Dykehouse.—In No. 116 of Work a writer deals briefly with wardrobes. You might gather sufficient instruction from his remarks serviceable to you. If you do not, however, a reference to Indexes of Vols. I. and II. will bring to your notice several details of wardrobes in "Shop" and elsewhere.—J. S.

**Colouring Clays.**—Workite.—The chalks are ordinary soft chalk. The depression made by a flat rose-cutter in a lathe, or a brace and bit, would answer. The cubing of the chalk may be done at a table with a circular saw or band-saw, a gauge, and two sides of a square; determine the cuts. Your experience of clays must show you how different clay is from chalk in its action under the effect of mixing with water, etc.—one, when dry, becomes hard and stony, the other remains soft still. There is no clay, such as pipe-clay, or very little, used in crayon making; the less the better. For black crayons, proceed as follows:—Take yellow wax, 32 oz.; curd soap, 24 oz.; washing soda, 1 oz. dissolved in water; Paris black, 7 oz. Mix gradually, adding to the heated mass as it burns the soda, and the black is stirred into it by degrees. Crayon making is a fine craft; many of the metals are blended with the chalk or calcium carbonate, as also, with some pipe-clays and china clays, gypsum, talc magnesium, bismuth, etc. The alcoholic solution of shellac, liquid gum, or turpentine are used for mixing. The best black for crayons is made from camphor into black; ivory black is also used. In working earths, chalk, or clays for crayons, reduce them to fine powder by triturating in water, and decant the liquor into a vessel for evaporating the water from the substances held in suspension. This is collected, and mixed with weak gum or other adhesive liquid into a stiff paste. It is then forced through dies, just as drain-pipes are made, on to an endless belt, a wire being used to cut them into lengths at the face of the die. For mixing to make coloured clays, use any coloured earths suitable, as umber, ochre, chalk, sienna, raw and burnt. For other colours use lakes. This is the name for almost every colour having chalk for its base—blue, green, yellow, purple, rose-pink, etc. These can be bought cheaper than they can be made, unless you have whiting, etc., to hand of which to make lake colours by staining them. I can meet with no clay-mixing books. Writers are so intent upon displaying their theoretical intelligence in chemical jargon that they omit the word clay from their writing about it. It is not in the "Encyclopædia Britannica," and the learned dunce constantly shows through the veneer of pseudo-scientific terms. A good English work on "Colours and Dyewares" is by J. W. Salter (Crosby Lockwood & Co., 7, Stationers' Hall Court, E.C.). Another, "The Dyer and Colour-Makers' Companion," by H. Carey Baird & Co. (810, Walnut Street, Philadelphia, U.S.A.); both low-priced works, I should think.—J. C. K.

**"Safety" Gear.**—J. P. A. (*Walthamstow*).—The gear of the Safety at present is 67½ in.—much too high for practical use. With ten teeth on the hub, the gear would be reduced to 54 in. The simplest method of lowering the gear would be to key on a lower chain wheel on the pedal shaft, say, fifteen teeth, which would gear with the present hub down to 56¼ in., or a chain wheel of fourteen teeth, which would gear down to 52½ in. To alter the hub cog-wheel would require a repairer, and a cog-wheel might not be got that would fit, in which case one would have to be made for it. Chain wheels can be had, any number of teeth, from 1s. 6d. to 2s., of the St. George's Cycle Co., Islington, London; or Brown Bros., 7, Great Eastern Street, London. There is no really practical arrangement for gearing while going.—A. S. P.

**Re-touching Medium.**—G.B. (*Edinburgh*).—An excellent re-touching medium is thus made:—Take 120 grains of gum dammar, and dissolve it in one ounce and a half of benzole, then add half an ounce of turpentine. When it begins to get thick by reason of evaporation, it may be thinned down by adding a little benzole and turpentine in the same proportions. There is seldom any necessity for filtering if the dammar is good. It may be broken up into a rough powder, put in a bottle, and the solvent poured over it.—D.

**Cleaning Silver Plate.**—F. W. J. (*Fulham*).—All silver is liable to discoloration on exposure to the smoke, fog, and gas-charged atmosphere of London. Pure silver is more liable to tarnish than alloyed silver. Electro-plated goods, being coated with pure silver, are more difficult to keep clean than goods made of sterling silver, but I do not know of any kind of plating which will resist the bad effects of an impure moist atmosphere. Silver-plated articles in show-cases in shops where gas is burnt soon go off colour, and show a number of dark specks where the gas-charged damp air has condensed on the cold metal. Wash the tarnished silver in soapy water, containing hartshorn, carbonate of ammonia, or liquid ammonia, then dry with soft linen rags. Brush engraved parts with a soft brush whilst in the liquor. This will clean tarnished plate with less wear than the use of plate-powder. Electro-plated articles dipped in kristaline will keep their colour for a longer time than those not coated with this preservative varnish. See "Our Guide to Good Things" on p. 202, Vol. III., of Work. —G. E. B.

III.—Questions Submitted to Correspondents.

**Printing on Tin.**—Curious will be glad to know the process or preparations used.

**Silk Weaving.**—Curious writes:—"How are silk-woven mantle or coat hangers made—*i.e.*, by what process and out of what material? And what is the name of the material used for 'stamped hat tips'?"

**Paper Wheels.**—W. H. K. (*Accrington*) writes:—"Can any reader give me information about the process of making boards and railway-carriage wheels, etc., from paper, or where I could get the information?"

**Fret Machine.**—Lancashire writes:—"In Work, No. 58, Vol. II., page 91, North Jack has sent drawings for a fret machine. I am making one, but don't understand how the saw frame is fastened at the back of machine so as to work. Will North Jack kindly tell how it is done? I want as perpendicular stroke as possible."

**Mining Engineering.**—S. H. M. (*Liverpool*) writes:—"Will anyone kindly send me all particulars of the profession of mining engineering? What is the course for it? what age does one enter? and what is the length of its course? Can certain kinds of mines be taken up *exclusively?* What number of examinations are there, and what are the colleges for it—at home or abroad? and any other particulars about it."

**Electric Gas-Lights.**—Strikalite will be grateful for instructions how to make an electric gas-lighter worked by frictional electricity; a diagram showing connections and dimensions will be useful. Also where the necessary clock-work may be obtained.

**Rifle Rack.**—A. S. (*London, S.E.*) writes:—"Will any kind reader of Work give me a few hints as to making a rifle rack, to take eight rifles, to fix to the pole of a bell tent, the same as one sees at Aldershot Camp in August?"—[A Gun Rack was given on page 60, No. 108. Why not convert it for your purpose?—Ed.]

**Gold Blocking (Cards).**—Curious asks:—"Is there any process (dry) whereby the gold can be made to adhere to the card until blocked, same as in the case of books? But the process must be such as won't soil the card; glair would not do."

V.—Brief Acknowledgments.

Questions have been received from the following correspondents, and answers only await space in Shop, upon which there is great pressure:—Excelsior; R. K. (*Brockley, S.E.*); R. P. C. (*Sunderland*); H. & R. (*Birmingham*); H. P. (*Bristol*); D. B. D. (*Glasgow*); W. F. (*Salisbury Square*); D. B. T. (*Dalbeattie*); J. S. (*Preston*); Ancona; W. G. (*Manchester*); E. A. (*Salisbury*); C. H. C. (*Hornsey*); Mercury; H. J. H. (*South Hackney*); J. A. (*Southport Lane*); Kinning Park; S. T. (*No Address*); J. T. (*London*); C. T. (*Edinburgh*); S. F. R. (*Edinburgh*); C. Bros. (*Leeds*); B. J. B. (*Boddington*); J. M. P. (*Preston*); Puzzled; L. G. (*Falmouth*); Adia; J. H. (*No Address*); G. W. S. (*Tufnell Park*); F. G. (*Paddington, W.*); Dundee; W. C. (*Shrewsbury*); Nemo; J. A. J. (*No Address*); J. W. H. (*Nottingham*); J. G. (*Sunderland*); T. S. (*Pendleton*); W. A. (*Faversham*); J. H. (*Holloway*); H. B. CASSELL'S SHILLING COOKERY.

# AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their **Improved Eclipse Cameras and Outfits**, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra.

These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.**, post free.

***A Wholesale Dealer's Stock-in-Trade at about Half-Price.***

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

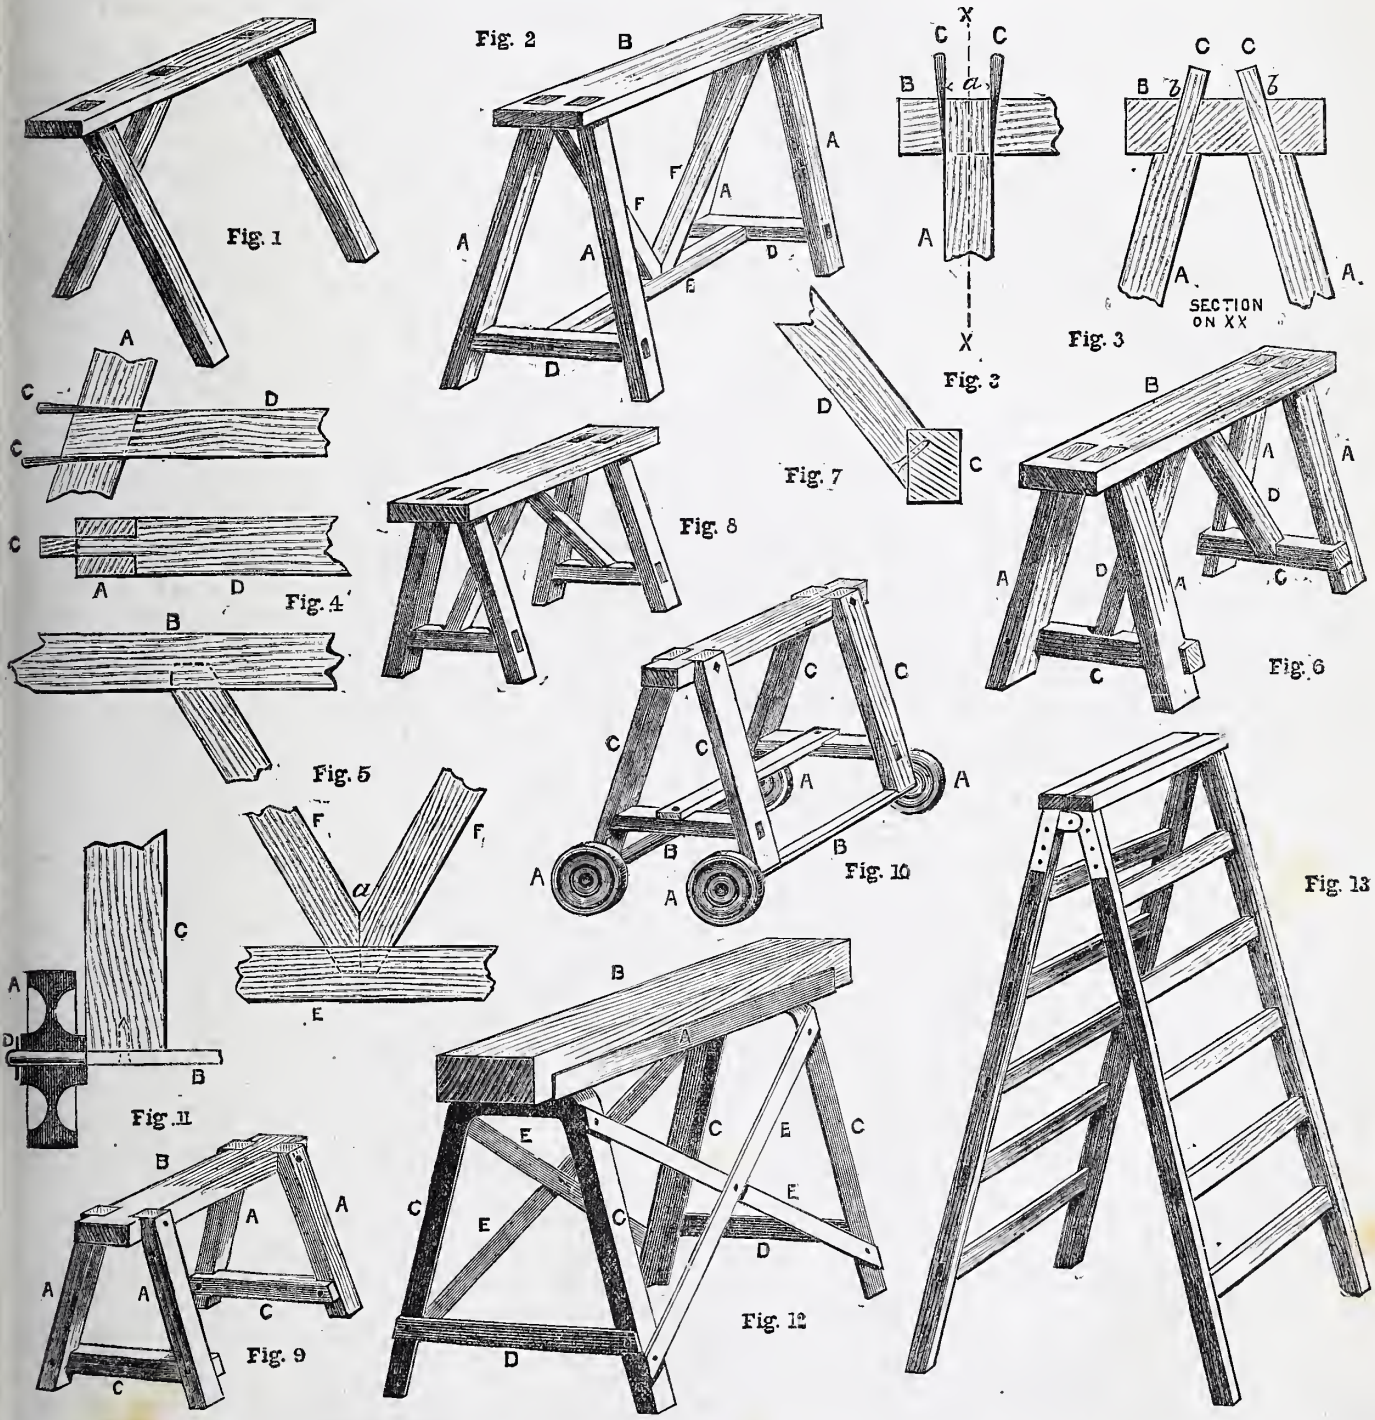
## An Illustrated Magazine of Practice and Theory

FOR ALL WORKMEN, PROFESSIONAL AND AMATEUR.

[*All Rights reserved.*]

VOL. III.—No. 126.] SATURDAY, AUGUST 15, 1891. [PRICE ONE PENNY.



ABOUT TRESTLES. Fig. 1.—Three-Legged Trestle. Fig. 2.—Typical Form of Trestle used for General Purposes. Figs. 3, 4, 5.—Details of Jointing. Fig. 6.—Trestle with New Mortised and Tenoned Joints. Fig. 7.—Detail of End of Strut. Figs. 8, 9.—Sawing Trestles. Fig. 10.—Trestle on Wheels. Fig. 11.—Detail of Wheel and Axle. Fig. 12.—Boiler-Maker's Trestle. Fig. 13.—Builder's Trestle.

## ABOUT TRESTLES.

BY J. H.

DIVERS FORMS OF TRESTLES—THREE-LEGGED FORM—TRESTLE FOR GENERAL PURPOSES—METHOD OF JOINTING—A SIMPLIFIED FORM—SAWING TRESTLES—TRESTLE ON WHEELS—IRON TRESTLE—TALL BUILDER'S TRESTLE.

*Divers Forms of Trestles.*—These occur in divers sizes, forms, and proportions. They are used by paper-hangers, carpenters and joiners, pattern-makers, boiler-makers and platers, and in many other handicrafts. An article on their forms and modes of construction may therefore be of service.

*Three-Legged Trestle.*—Fig. 1 shows the simplest and also the most unsteady trestle that can be made. It has but a limited use, being employed chiefly by paper-hangers and glaziers, who lay boards across two such trestles, and cut their paper or glass upon the boards. These must be used in pairs. A single three-legged trestle would be too unsteady to be of any service.

*Trestle for General Purposes.*—A very generally serviceable form of trestle is shown in Fig. 2. Quartering of light or heavy scantling may be used, according to the purpose for which such a trestle is required, and the method of framing together may vary, but the type is useful for supporting almost all kinds of work, from a common washing-tub to a piece of joinery or pattern-work in course of construction.

*Method of Jointing.*—The trestle in Fig. 2 is framed together with mortises and tenons in a workmanlike manner as follows.

The four legs, A, A, A, A, are mortised into the top, B. The detail of the method is shown in Fig. 3. The mortise in B is cut longer than the width, *a*, of the tenon of A, to allow of the driving in of wedges, C. The complete joint thus assumes a dovetailed form, wider at top than at bottom, and the legs, therefore, cannot fall out. The wedges must be driven in as shown, against the *ends* of the tenon and the *end grain* of the top, B, and not against the flanks, *b*, of the tenons. If they were driven against the flanks, *b*, they would split the top, B.

The stretchers, D, Fig. 2, are mortised into the legs, A, as shown in Fig. 4, with wedges, C, driven against end grain, as in the previous instance. The longitudinal stretcher, E, Fig. 2, between these short stretchers, D, is also mortised in the same fashion.

A trestle made thus with close joints will stand a considerable amount of rough usage. If the legs were short and the scantling of large section, as in the case of a sawing stool, strutting would not really be necessary. But it is always advisable to strut high trestles made of slight scantling, say not exceeding 2 in. by 2 in., or 2 in. by 2½ in. cross section. In Fig. 2, struts are shown at F, F. Though it is necessary that these struts be mortised into B and E, the tenons will not pass through nor be wedged.

It is quite enough to stump tenon the ends of F, F, Fig. 5, at top and bottom. Note the abutting of the two struts at *a*—a further steadiment to the framing. If these shoulders are all fitted closely, and if the tenons make a tight driving fit, the trestle, when glued together, will be as firm as a rock.

*A Simplified Form.*—There is, however, a simpler method of framing trestles of this type together. It is shown in Fig. 6. The only members that are mortised are the legs, A, into the top, B. The cross stretchers, C, are simply let for about ½ in. into the legs, and screwed, or, preferably, secured with small bolts. The struts, D, are stump tenoned into the top, but at the other end they are merely shouldered back to fit over the stretchers, C, Fig. 7, and screwed or bolted. For a trestle of somewhat heavy scantling, like that shown in Fig. 6, this simpler method of jointing is quite good enough; but for a lighter trestle, like that in Fig. 2, the method of framing together with longitudinal bottom stretchers, E, and mortised joints throughout, makes a more steady job.

*Sawing Trestles.*—Figs. 8 and 9 show the low form of stool used chiefly for sawing boards upon. These are about 20 inches in height, and firm and stiffly made. In Fig. 8 all the parts are mortised, and tenoned, and strutted in workmanlike fashion, as in Fig. 2. But in Fig. 9 nothing of this kind is done. Here the legs, A, A, A, A, are simply shouldered into the sides of the top, B, and a single bolt passes through each pair of legs and the top. The cross stretchers, C, are slightly shouldered back, and screwed or bolted to the legs.

*Trestle on Wheels.*—A form of trestle that I have used for several years, and found very handy for heavy pattern work whose position in the shop sometimes requires to be shifted, is shown in Fig. 10. It is useful also for pushing heavy timber along to the circular saw. It is simply a strongly-made trestle mounted upon small iron rollers or wheels, A. The detail of the latter, with their axles, is shown in Fig. 11. The axles, B, are rectangular bars of iron of oblong section. These are screwed to the bottoms of the legs, C. The ends are forged or turned down to circular section to receive the wheels, which are kept on with a pin, D. The wheels are castings, about 6 in. in diameter, and dished or hollowed out on each side for diminution of weight.

*Boiler-Maker's Trestle.*—Fig. 12 shows an iron trestle, used by boiler-makers and platers, fitters, fettlers, and others in the engineering trade. This also is made in different sizes and scantlings, but the figure gives a good idea of what we may call a standard type. In this, A is a piece of channel iron of suitable section. Into this is fitted a length of a deal, B, somewhat longer and deeper than the iron. Pieces of bent angle iron, C, form the legs; they are riveted underneath to the channel iron. For light work pieces of flat bar iron may be used instead of angles, but of course they are not nearly so rigid as the angles; but then the trouble of bending angles is saved. The angles, C, are rendered rigid in one direction by riveting the stretchers, D, across, and in the other direction by riveting the diagonals, E, both to the angles and to each other where they cross at the centre. The result is a perfect trestle, strong, rigid, and everlasting. In an engineer's yard the cost of making these is but slight.

*Builders' Trestles.*—Fig. 13 shows tall trestles used in pairs by builders, carpenters, engineers, and others, for laying planks upon for the building up and the erection of work. The uprights are hinged at the top, and planks are laid along upon any of the cross-bars whose height happens to be most conveniently situated for the work in hand.

Thus I have endeavoured to group together the various kinds of trestles that are chiefly in use in the building and other trades, and describe their construction in the hope that this little monograph on the subject will not be without its use to the readers of WORK, professional and amateur.

## FRENCH POLISHING: GLAZING.

BY DAVID DENNING.

DIFFERENCE BETWEEN SPIRIT AND GLAZE FINISHES—REAL OBJECTION TO GLAZING—LESS PRACTICE REQUIRED—GLAZING OF ADVANTAGE IN INLAID WORK—OTHER CASES IN WHICH IT MAY BE USED WITH ADVANTAGE—GLAZE TO BE BOUGHT READY-MADE—HOW TO MAKE IT—GUM BENZOIN—HOW TO APPLY GLAZE—REVIVAL OF OLD FRENCH POLISH WORK.

AT the close of the article on Spiriting-Off in French polishing, one on finishing by means of glazing was promised to readers, and it will be of special use to those who are unable, through want of time, to learn the better process, or who want to finish any polished article with the smallest amount of labour.

The difference between the spirit and glaze finishes may be described as being in the one case by friction, and the other by the addition of a thin fine varnish to the surface of the body of polish. In the former case the polish itself is polished; in the latter it is varnished with a mixture known commonly as glaze, but to which other names, such as slake finish, are sometimes given. As may readily be surmised, finishing by means of glaze is not so good as the legitimate method by spiriting, and can hardly be considered as being anything more meritorious than a means of getting the same effect easily and quickly—an imitation, in fact, of the real thing.

Why, then, it may be asked, should space be devoted to telling people how to imitate good French polish? And it is more than likely that some professional polishers may object to an explanation of what may almost be called one of the "tricks of the trade."

Even if it be granted that glazing is an imitation, it has such a recognised acceptance among polishers, is so remarkably convenient occasionally, and in some cases possesses an advantage over spiriting, that it may fairly be classed among the ordinary processes of polishing. When done in moderation, I, for one, can find no fault with glazing, which I hold to be just as useful as, say, the application of spirit varnish on the carving of a piece of work said to be, and justly considered as being, French polished. These remarks, I think, are sufficient justification to those members of the trade—were any justification necessary to such people—who do not believe in letting the public know too much. The only thing in connection with glaze that may be reprehended is the finishing of whole pieces of carcase work with it, to delude purchasers into the notion that it is French polished; or, if this is too much to say—for the work is really French polished—that it is finished in the best manner. The real objection to glaze finish is that it is not so durable as the other, for at first the appearance is equal to that got by any other process. It may even be said to be superior to badly spirited finish, and herein consists the chief claim it has for notice by amateurs. With all due respect for their skill, it is seldom that any of this class of worker can manage to do spiriting thoroughly, for the simple reason that they have not sufficient opportunity of acquiring practical experience.

Glazing does not require so much practice, so that, comparing it with finishing by spiriting off, results certainly equal to the latter, and probably superior, will be got with the former by inexperienced people. The practical polisher, of course, will learn glazing in the ordinary routine of his work, and must judge for himself when its use is

legitimate or not. Without putting myself up as a commercial moralist, I should unhesitatingly say that when a customer will not pay more than a sovereign for polishing a job on which good polishing might fairly cost double, the polisher is fully justified in using as much glaze as he likes. Perhaps it would be just as well to explain the difference to the customer, in order to give him an opportunity of having the work done well.

As any one who has had any experience in the furniture trade knows, though, there are some buyers or customers who always want to get work done for half its value. Knowing any one to be such, I do not think it would be worth the polisher's while to explain to him—or, more probably, her—anything about different methods. Perhaps the most delicate way of giving the information would be to send the number of WORK in which this appears to the "other party" in the transaction. I am a believer in letting people know what they are getting for their money, and if they are content to have a glazed finish, the onus of supplying it is off the polisher's shoulders. I therefore do not see why any unprejudiced polisher should object to easy processes being told any more than to those which are more difficult. Any way, my duty to the publishers of WORK and the readers who look to it for information impels me to tell all that is likely to be useful.

Among respectable polishers who can command a reasonable price for their work, glaze is of comparatively limited application, and is confined to those parts of a job where the spirit rubber cannot be conveniently used, or where its use is not necessary. Instances of such may be found in chair rails and various parts of the frame. This, as is no doubt well known to all engaged in the furniture trade, is usually polished to a greater or smaller degree before it is upholstered, or at any rate, before the outer covering is put on, the finishing being almost necessarily done last of all. The less the chair is handled then by the polisher the better, especially if the covering is a delicate one, for it does not require any practical experience to perceive that there is less risk of injury with one or two wipes over with the glaze rubber than with the more prolonged spiriting.

Another instance where glaze may be used with advantage is in inlaid work, where the inlay is slightly, though perhaps not intentionally, a trifle higher than the surrounding wood. In such a case I think most polishers will agree with me that it is better to resort to glaze than to finish with the spirit rubber. On fretwork also glaze may often be used with advantage, but remarks about this must be reserved till later on, when I shall have something to say specially applicable to fret-polishing.

As a rough guide to those who do not know when glaze may be used without risk, I may say generally that it is unobjectionable on parts which are not subject to wear and tear. It will stand a moderate amount of handling, but not so much as good hard spirited off polish; and even when left alone the lustre is not so durable. Beyond this it is almost impossible to define the extent to which glaze may be used on work which is intended to be really of the highest character, and every one must use his own discretion as to its application.

Glaze under one or other of its different names, some of which are specially given to their own preparations by manufacturers, may be bought ready made, but for similar reasons to those given in connection with French polish, the home-made article is to be recommended. The preparation of glaze is equally simple, the ingredients being gum benzoin and methylated spirit. The proportions may vary, but those given for polish will do very well, and with the substitution of benzoin, which should be crushed, for shellac, the process is exactly the same. After the benzoin is dissolved, the solution should be strained through muslin to free it from impurities in the shape of pieces of twig and similar foreign matter.

Gum benzoin—or, as it is sometimes called, gum benjamin—differs greatly in quality, and it is almost needless to say that the best should be used by the polisher. Compared with lac, it is expensive, so that the saving which is attributed to its use is mainly in time, which readers need hardly be reminded is, from a trade point of view, money.

As some guide to quality, it may be said that the whitest sample should be chosen; and I have been given to undertand that, as the light benzoin is better than the other, white lead is used as an adulterant. White lead, it need hardly be said, is not a recognised ingredient in any of the French polisher's preparations, so that benzoin containing it cannot be considered fit for his use.

Certainly cheap benzoin is not be relied on, and in a strange place I would look with suspicion on any offered to be sold in ordinary retail quantities at much under 2s. 6d. per lb., however satisfactory its appearance. In this, as in other cases where anything is liable to adulteration, the best way to avoid imposition is to go to a reliable dealer and to pay a fair price.

As "patent" benzoins are sold at a very much lower price—one kind, I believe, as low as 6d. per lb.—some may be tempted to buy them. That they are much used there can be no doubt, so it may be presumed some polishers find them satisfactory. I can only say that personally I do not recommend them, unless perhaps when extreme cheapness is the main consideration.

They—I refer to the only two "patent" benzoins which have come under my notice—form glazes which are liable to crack, and one of them especially is such a bad colour that its use on light wood is not beneficial. There may be more patent benzoins than those I have alluded to, and if I meet with a satisfactory one I shall have no hesitation in speaking favourably of any good qualities it may possess. Meanwhile, I prefer the genuine article.

Glaze may be applied with rubber, sponge, or brush, and in the majority of cases the first named medium is the most suitable and that most commonly used. It is made in the ordinary way as if for polish, but if anything softer, as glaze, must not be applied with pressure. It is rather painted on than rubbed into the work, which, to prevent any misapprehension, I repeat must have been previously bodied in. I am particular about this, as there seems to be a sort of idea prevalent among amateurs that glaze or "something" can be put on bare wood and cause a gloss right off. Let me say that there is nothing of the kind, and that a polish cannot be got on wood, except by varnish, by any other means than one of those indicated.

When using glaze, the rubber should be made wetter than when polish or spirit is used; but still, there should not be sufficient to drip from it. What is wanted is to glaze or wet the wood when the rubber is very lightly pressed on it. One or two wipes over, always in the direction of the grain of the wood, with a somewhat quick motion, though not by any means a "slap-dash" one, will put the glaze on, and on no account should the rubber be passed over a wet surface. Always let the previous one be dry before applying the rubber again to the same place. The defect that will be caused if care in this respect is not taken will be so obvious to anyone who makes the attempt—which he may as well do on a piece of waste wood, by way of experiment—that nothing need be said about it further. The coats may be repeated till the gloss is satisfactory, but the film of glaze should never be a thick one.

If a sponge is preferred, it is used exactly as a rubber would be, and on the whole it is questionable if there is any advantage gained by using sponge. Like a good many other details in connection with polishing, it is a matter of fancy.

When a brush is used the glaze may be regarded as a varnish pure and simple. With a brush a mixture of glaze and French polish, either white or brown according to the work, in equal quantities may be used with advantage, though on this point there are differences of opinion, chiefly, as far as I have been able to observe, arising from the nature of the work the polisher is most accustomed to.

If the glaze is not quite so satisfactory in appearance as it should be, it may sometimes be improved by passing a spirit rubber lightly over it, though this should only be done with great caution, to avoid washing the glaze away. When carefully and skilfully done, there can be little doubt that a glazed surface may be often, if not always, improved by slightly spiriting it.

It may be a useful bit of information to many that old French polished work may often be "revived" by being lightly gone over with glaze after the surface has been washed and cleaned with warm water. This treatment is at least as beneficial and often considerably better than that so commonly adopted with furniture pastes, polishes, creams, and revivers of various kinds, all of which will be dealt with in due course.

## WIRE-WORK IN ALL ITS BRANCHES.

BY JAMES SCOTT.

### SCROLL IRONS—"GOTHICS."

Now I must make it my business in this paper to refer to and explain the use of what are called "scroll irons." On the top of fencing, baskets, etc., it will be observed that some of the wires often terminate in a scroll. In instances where they are practicable the remarks which here follow will be applicable.

To the bench are secured, by means of fasteners, irons of the shape shown in Fig. 64, or of any pattern desired. The inside point of the irons (A in Fig. 65) must terminate sharply, for to this point will be hooked, as it were, the end of the wire to be bent. Then the wire is drawn tightly along the outside edge of the scroll iron, and pressed evenly and firmly against the latter. All the fasteners, let me say, must be brought on the inside edge of the scroll iron, in order that the outside edge may be quite level.

Wire-workers who have had much practice do not require the aid of scroll irons for performing this kind of work; and I

have seen my practical friend bend small and large scrolls in clean nice lines with the humble assistance of only the pliers, and, indeed, in some cases by merely using the fingers. But it is hardly reasonable to expect that any of my numerous readers, other than those who are or have been accustomed to wire-working, shall possess sufficient ability to accomplish the completion of wire scrolls by the help of only the fingers or pliers.

As it is possible that many who read these lines may be interested in practical fretwork, and as it is also probable that many of them may wish to try their hand at a bit of wire-working, I think it may be as well to say that, in the place of scroll *irons*, scrolls of hard wood of sufficient thickness *screwed* to the bench could be used with almost the same facility.

For the purpose of bending wire any curved shape, other than that of a scroll, it is also serviceable to have irons or fretwork of the line required.

If a rather large piece of work is in hand, and it is considered inconvenient to make the scroll terminals at the commencement, sufficient length of wire should be left for the purpose until the remainder is completed. The job can then be held against the side of the bench vertically, and the wires finally bent round the scroll irons; but in this case it is, of course, necessary that the latter be near the edge of the bench, whereas, if the scrolls are always to be made at the beginning of a job, it matters little upon what part of the bench the irons are situated, provided they are handily within reach.

It will be understood that this alternative of leaving the scroll work until the completion of the remainder is only necessary when the scrolls are in a position cross-wise to the length of the job, but that when they follow the length of the work the scrolls can be made at the beginning.

"Gothics" is the name given to wires when bent after the shape of Fig. 68. Those who have the smallest knowledge of architectural styles will notice that the title is an apt one.

This kind of ornamentation is largely introduced amongst articles in wire, embellishing the tops of them, although they are capable of being treated in what might be termed an artistic manner in adapting them as panels, by securing four or more in a geometric position, after that represented in Fig. 66.

In a piece of work along which a series of gothics are required, there is no need whatever that each gothic shall be separately made from the remainder. Of course, irons or fretwork may be used in the same way as scroll irons. Supposing separate gothics are required, the best course will be to cut up a number of wires, each of sufficient length to make one gothic and permit of its ends being bent round the work which it is to ornament; but where a series are required the wire need not be so cut: all that needs to be done is to proceed as in Fig. 65, bending the wires in consecutive gothics, afterwards bringing their tops and bottoms into a straight line.

It frequently happens that it is preferable to have the gothics slightly bent instead of being perfectly upright. This is nearly always the case when any circular piece of work is in hand. When this is so, it is only necessary that the gothics, thus far complete, are placed upon or below a cylindrical surface, and bent to the shape of it. It is best to do this while the whole of the gothics are in a straight line, for then it is more probable that each of them will be bent to the same degree as the remainder, and the two ends of the whole can be brought together and secured, if a circular piece of work is required.

For this secondary bending it is preferable to have metal tubes or rods, but, as a makeshift, wooden or other substitutes could be appropriately utilised. The sweep of the curve obtainable will depend upon the diameter of the article around which the gothics are bent; thus, if worked over something which is but one or two inches in diameter, the curve will be a sharp one, but if the diameter be about six or seven inches, the result will be but a very slight curve.

The above remarks apply where the whole of each gothic is bent from the straight; but now and again it may be considered preferable to merely bend the top over. In such cases as these the same particulars will hold good, excepting that only that portion required to be bent must be placed over the cylindrical surface.

There are other ways of obtaining these gothics. One of them is to bend each portion of wire which is to compose one of them round a half-circular block instead of a gothic-shaped one. Each half circle should then be bent at the point A (Fig. 68), bringing each half closer together, and at the same time frontwards.

The other method is to bend the whole length of the wire to be "gothicked," as shown in Fig. 69, in which diagram the wire is supposed to be laying flat. If each of the upper projections is then bent upwards or outwards, it will be found that when they are drawn apart at A, A the result is precisely the same as that gained by proceeding by means of either of the other two modes.

## A USEFUL COMBINATION BEDROOM SUITE.

BY CLERICUS SECUNDUS.

Nature of Suite—Its Prototype—Length of Table-Bed—Material—Legs—Cross Pieces—Putting Skeleton Together—Panels and Panel Framework—Planks for Head and Foot—Flooring for Mattress—Side Planks—Finishing Cupboards—Floor—Top—Desk Top—Frames—Sections and Leather—Completion.

In Vol. I. of Work a description and design are given of one of the most ingenious articles of furniture I have seen for some time, and one which should "come as a boon and a blessing to men," or such of them as by duty or necessity are cramped in the matter of living room. Looking over the design, and thinking of those whom it was

chiefly intended to benefit, the idea flashed across me: But what of the sleeping accommodation?—for among its multifarious uses this combination does *not*

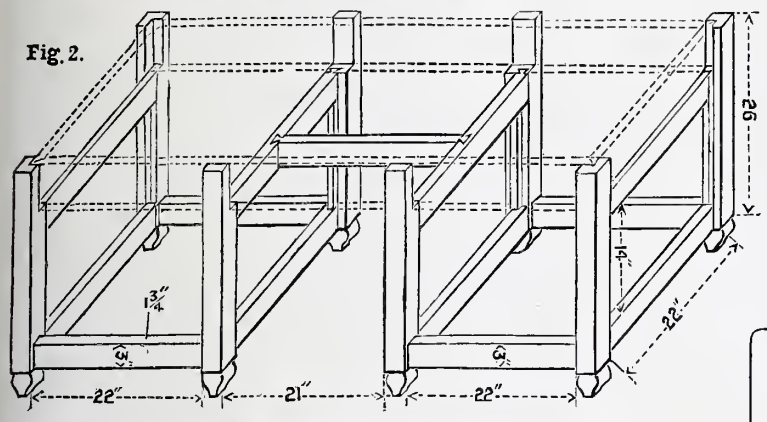
> "Contrive a double debt to pay:
> A bed by night—a chest of drawers by day."

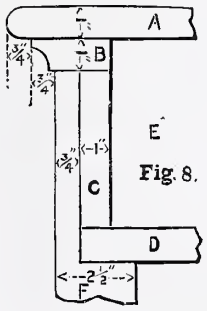
True, the possessor thereof may have a separate sleeping apartment, but in that case the contrivance is hardly necessary; and if not, to be able to stow away one's brush and comb—even including the et-ceteras—when one's bed is exposed to the public gaze, is a rather doubtful advantage.

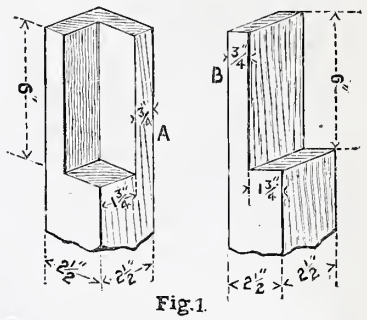
It was whilst cogitating on this knotty point that I remembered having heard of, or seen advertised, a combination of library-table and bedstead, which seemed to me to exactly meet the needs of the case.

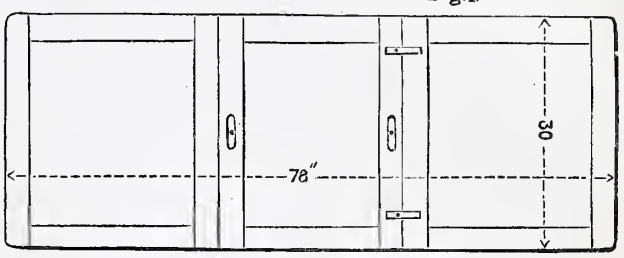
The inventor and patentee is a Mr. Zwicker, of Brussels, and anyone wanting the complete and thoroughly finished article had best apply to him. As Mr. Z. has obtained protection for his desk in England, it might be dangerous for any maker to reproduce it for purposes of sale. Amateurs, however, may safely make one for themselves on the lines herein laid down, as, never having seen Mr. Zwicker's arrangement, there is, so far as I know, nothing in common between the two, except the utilisation of the library-table for sleeping purposes, and the transformation of a part of the desk-top into a table. Furthermore, being "only an amateur," and not much of a one at that, I have no pretensions to teach my superiors in matters mechanical. I write only for the benefit of such amateurs as may be doubtful of their abilities for such a task, for they may be sure that where I lead anyone can follow; the result being, I trust, a piece of furniture which will be no disgrace to any room, whilst it will be found convenient, not only by the young men compelled to live in chambers or hired rooms, but even amid the more complete appointments of the settled home, if only for the accommodation of some member of the family when a "little stranger" or a bigger, if not more welcome, one arrives.

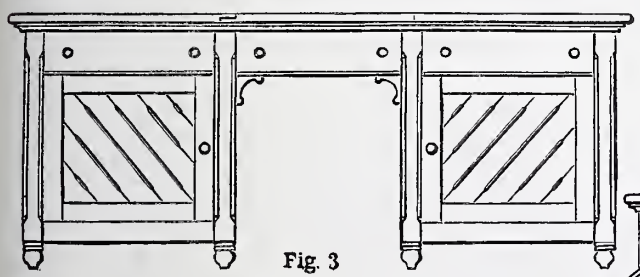
But before setting to work, two questions must be settled: Firstly, what shall be the length of the desk? We are not anxious to modernise the bed of Procrustes, whilst a bed 6½ ft. long for a man who stands five feet nothing in his socks is sheer waste of good material. Let each man take his own measure (a most difficult operation), and cut his wood accordingly. The desk here designed is meant for a fairly tall man, and gives nearly six feet of mattress. Any alteration in this particular will simply entail a corresponding alteration in the working plans. Secondly, what shall the desk be made of? Here another unknown quantity stands in the way of a correct solution—to wit, the length of the maker's purse. This too, then, he must settle for

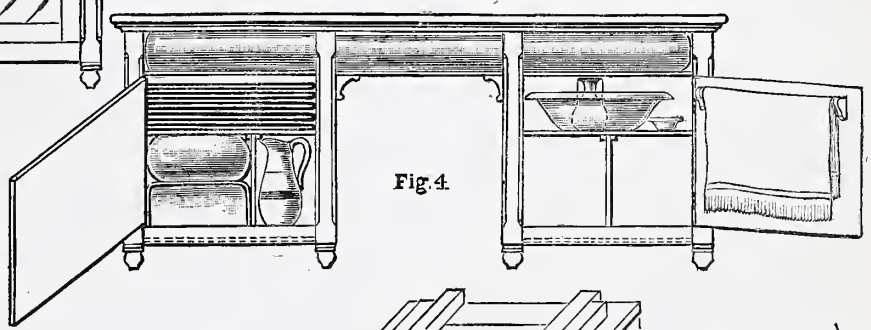


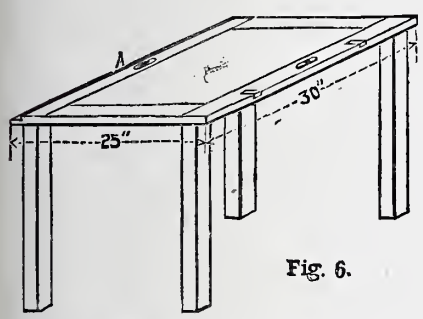












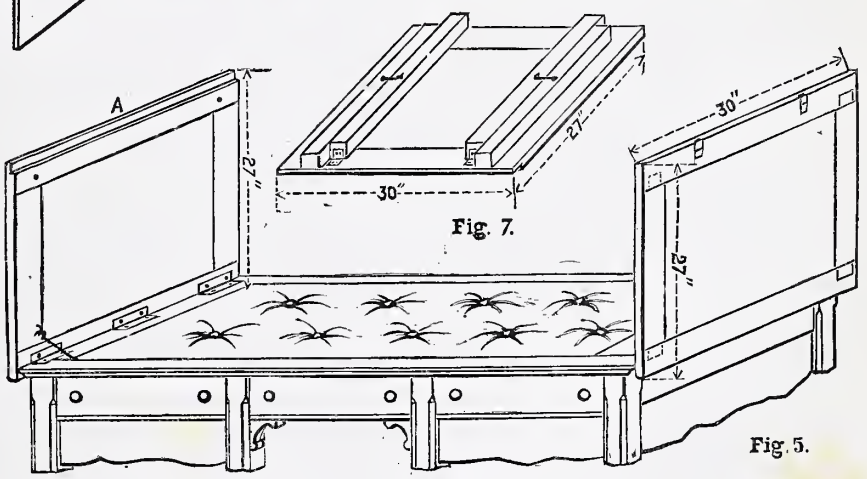


**Fig. 1.—Shaping of Legs at Top for Corners (A) and for Sides (B). Fig. 2.—Skeleton of Desk. Fig. 3.—Elevation, Front and Back. Fig. 4.—View of Interior, showing Arrangements. himself. Oak, walnut, mahogany, good pitch pine, have all their qualities and recommendations, but the supposition being that the amateur belongs to that large class which does not suffer from plethora of money-bags, the last named material has been in the writer's mind when drawing out the accompanying plans. So now to work!

We shall need eight legs 2½ in. square and 2 ft. 6. in. long, finished size. Four of them will have to be shaped at the top like, A, Fig. 1, for the corners, and four like B, Fig. 1, for the sides. The feet will have to be turned; they stand 4 in. high. Should the maker not have a lathe, and wish to do the whole work himself, the feet may be dispensed with, and a skirting-board, with a simple moulding at the top, run completely round. In that case the bottom cross-pieces should be tenoned into the legs nearly at the ground level, and the sides of the cupboard lengthened accordingly. Thirteen cross-pieces will be needed, all 3 in. wide. They should be as follows:—ten pieces 22 in. long, 1¾ in. thick; one piece 21 in. long, 1¾ in. thick; two pieces 22 in. long, 1 in. thick.

Let us begin to put together the skeleton of the desk. It will perhaps be best to first bind the front and back legs together. Pair them and arrange them in sets of four as they stand in the completed article. In marking for tenon and dovetail, a little care will be needed to prevent mistakes. Bear in mind that in each place the fixed cross-pieces must be flush with the *inside* of the cupboards; this will give us on the outside recessed panels ¾ in. deep. The bottom cross-pieces must be tenoned, the upper either tenoned or dovetailed, the latter preferably. The 1 in. thick cross-pieces are meant to be upper and outer ones. The cross-piece 21 in. long must be fixed across the leg space to hold the cupboard frames together. This is to take the strain partly off the sides and flooring of the mattress space, which otherwise would have to be wholly responsible for keeping the parts together should the desk need to be moved about.

Fig. 2 will, I think, make the arrangement of the cross-pieces perfectly clear. It will also show the grooves in the corner legs and the ledgers which are fastened to the middle ones, all being flush with the *outside* of the cross-pieces. These are to take the panels which form the sides of the cupboard. It will be observed that the 1 in. thick cross-pieces are reduced to that thickness in order to leave the grooves free for the end panels to be slipped in.

I have endeavoured to draw all the designs to scale, but not being a draughtsman, I have in each case added the dimensions for fear of error.

When all the legs and cross-pieces have been cut and fitted, they must be taken apart, the legs stop-chamfered, and the whole jointed up firm and tight. The end panels had next better be prepared. They may of course be plain, but as our desk is not overloaded with ornament, the planks which form the panels had better be stop-chamfered and fixed diagonally (see doors of cupboards, Fig. 3). The panel framework must be ¾ in. thick (the cross-pieces being tenoned into the uprights), and the panel proper of ⅜ in. wood and let into a groove in the framework. The dimensions, assuming the grooves in the desk-legs to be ½ in. deep, will be 17 in. by 23 in.

The panels having been slipped into their places, the planks at the head and foot of the mattress must next be fixed. They must be 2 ft. 1½ in. long, 6 in. wide, and 1 in. thick. The ends, instead of remaining square, must be bevelled off to an angle of 45 deg., so as to form a mitre with the planks to form the sides. They may be screwed to the legs from the inside. When fixed, the end planks will come right down on the framework of the panels, which, as will be seen, is not the case with the side planks.

The "flooring" for the mattress must now be prepared. The requisite dimensions will be found to be: Length, 5 ft. 11½ in.; breadth, 2 ft. 1½ in. It must be made of 1 in. wood, jointed in any safe way within the worker's powers, dowels and glue being perhaps as good as any. This must be dropped into the space left by the legs, and firmly screwed down. It will be amply supported in the centre by the cross-pieces underneath, and in my estimation likewise at the ends. In consequence, however, of the end planks being 6 in. wide, only ¾ in. of the cross-piece is available as a support. Should this be deemed insufficient, a ledger may be fastened to the end cross-pieces to increase their width. A cross-piece might also be fixed across the cupboard space similar to that across the leg space, if it be deemed safer to support the flooring along the whole length of its central line, but this appears to me to be superfluous.

The side planks must now be fitted. They must be 1 in. thick, 6 ft. 11½ in. long, and 5 in. broad. They will rest on the flooring, allowing the (inch-thick) edge of the flooring to be seen both front and back (see Figs. 3 and 5). The object of this is of course to represent the bottom planks of the drawers' space which would be there under ordinary circumstances. To carry out the illusion. drawer-knobs are fixed along the front. These can be readily purchased and glued into a hole bored with a centrebit. Four other knobs will be required for the cupboard doors.

It is immaterial whether the next process be the finishing of the cupboards or the fixing of the top. Let us take the former. The end panels being already fixed, the inner ones have to be placed. Nail ledgers to the top and bottom cross-pieces, flush with the *outside* (there are already some on the legs), and fill in with glue-jointed panels, which may be ½ in. thick. Dimensions, 22 in. by 14 in. For the floor, ledgers must be nailed to the four bottom cross-pieces of each cupboard—on the inner side, of course, and as near the bottom as possible—and the floor of, say, ¾ in. wood, glue-jointed, be dropped in. Dimensions, 22 in. by 22 in.

Fig. 4 will show the proposed internal arrangements. The left hand cupboard contains the bed-linen, the pillow, the bolster, and the water-jug. The other cupboard may contain the basin, water-bottle, and all the other bed-room and toilette requisites.

Of course, the maker will please himself in all these particulars, the shelves and partitions being held by glued blocks or ledger in any case. He will be guided in the matter by his special needs, and if he possess the "combination suite" already alluded to, or any other facilities for stowing away his bed-linen or other bed-room paraphernalia, the cupboards may be utilised for their more legitimate purposes. The object, however, is to make the desk-bedstead as complete in itself as possible, and the arrangement as sketched will be found convenient.

The doors call for no special mention, being made like the end panels, and as to size, 22 in. by 17 in. Of course, the appearance of the whole (see Fig. 3) will much depend upon the exactness of the work put into the panels. The doors must be hung upon butt hinges let into the legs and into the thickness of the door frames, the joint of the hinge being outward. It will be found more convenient to have doors front and back, though, of course, fixed panels may be substituted for one set of doors.

Now comes the top. Procure two lengths of 1-in. wood, 6 ft. 4½ in. long and 2½ in. broad, also two lengths 2 ft. 4½ in. long and 2½ in. broad. Along the outer edge of each of these run a simple moulding such as that shown at B, Fig 8, and mitre them at the corner, the moulding being underneath. Screw this moulding firmly to the frame of the desk. It should fit close to the leg top and the planks surrounding the mattress space, and project ¾ in. all round.

We now come to the desk-top proper. This, as will be seen on reference to Fig. 9, is made in three sections, the two outer ones being hinged to the moulding just fixed, the centre one being removable (see Fig. 5). The framework of each of these sections must be of 1-in. wood, and we will need for their construction the following:—Five pieces 30 in. long, 5 in. wide; one piece 30 in. long, 6 in. wide; four pieces 20 in. long, 5 in. wide; two pieces 17 in. long, 5 in. wide. The last mentioned six pieces, having to be tenoned into the others, have 2 in. extra allowed for a 1-in. tenon at each end. Now run a ½-in. rebate along those sides of the pieces which when fitted together will form the *inner upper* sides of the frames. This is for the purpose of afterwards fitting the leather or cloth-covered panels. Proceed to tenon the shorter into the longer pieces, putting the 6 in. wide piece to the left of the middle frame. Next form a 1-in. rebate on the under right hand side of the left hand frame, and another on the upper left hand side of the middle frame (see A in Figs. 5 and 6).

Now come the panels which are to fit into these frames; ½-in. wood, which must be glue-jointed, will, when planed down, do well if the rebate has been made exactly ½ in. deep, as the panels *when covered* should be flush with the frames. This at least is essential, and must be seen to. The exact dimensions should be, for the end panels, 18 in. by 21 in.; for the middle, 15 in. by 21 in. They must not, however, fit tightly, as allowance must be made for the thickness of the material with which they are to be covered. What shall this material be? Leather, if it can be afforded, and especially if the desk be made of one of the more valuable woods. In that case you must put a coat of paste evenly on the panels, lay the leather on, and press from the centre outwards. Afterwards the edges must be pasted down. For a desk made of the cheaper materials, however, I consider that green cloth or baize will look and answer quite as well as leather, and it has of course the advantage in the matter of cost. This must be "shrunk" by being wetted and dried, and then proceeding as just described. I would, however, advise glue rather than paste, and not too liquid, or it will show through the material. With their covering the panels should fit pretty tight, and a few small screws into the rebates from the under side will suffice to hold them in place.

The two larger sections must now be hinged on to the moulding as shown in Fig. 5. See to it that the hinges are of a size to come well over the moulding, for otherwise the piece of moulding might be torn away. They should certainly not be

less than 3 in. across when open, and may well be wider. Let them into the wood both of the table and of the cover, and see that the joint of the hinge is well to the edge of the moulding. They should be so fixed as to allow the "flap" to open until it stands at right angles to the desk, and no more (see Fig. 5). A hook may be fixed as shown to take off the strain and also to prevent the flaps from falling back on the occupant of the bed. When closed the left-hand flap should be fastened down with a couple of hooks and eyes, the hooks being attached to the inside of the sham drawer fronts.

On the longer sides of the centre section are drawn (Fig. 9) contrivances to serve as handles. They are made of brass, and consist of a small, shallow, oblong tray with a flange all round and a bridge across. The flange serves to screw them flush with the table top and the bridge to hold by when lifting off the top. These, if not readily procurable, may be replaced by some other contrivance, or for that matter dispensed with altogether. There are also two small brass bolts which are let into and lie flush with the wood. As the central section must be fastened to the right hand flap, these bolts, or something similar, are essential.

To cover over the bed and form the desk top, the left hand flap is lowered and fastened down, the rebate of the central section is slipped under the rebate in the closed flap; the right hand flap is then lowered and bolted to the central part.

Should the amateur prefer it, the rebates which interlock the left hand and middle sections may be done away with, and in that case the left hand piece of the middle framework will only be 5 in. wide instead of 6 in. The right hand flap must then also be provided with some means of fastening it down, and the two flaps will have to be closed before putting on the middle section. The latter must in that case be provided with bolts on the left hand frame as well as on the other.

If the amateur is fairly off for furniture, the desk may now be considered completed. If, however—as is more likely—his office or study is not encumbered with too many tables, Figs. 6 and 7 contain a suggestion which will be welcome. Get four pieces of wood 2 in. square (if a little less, it does not matter) and 22 in. long—less rather than more. Hinge these pieces on to the reverse side of the centre section of the desk-top, arranging them as in Fig. 7. The hinge end of the outer leg must be 3 in. from one side, and those of the inner legs 3 in. from the other. Note also that the outer legs must be $2\frac{1}{2}$ in. *full* from the edge, say $2\frac{3}{4}$ in.

A small bolt had better be fixed on, say, the inner legs, the socket being fixed on the outer. The bolt when shot will prevent the legs from swinging about when the table is lifted on and off.

When on the desk, the legs will lie along the side of the mattress, which must be stuffed very hard indeed if it does not "give" sufficiently to readily accommodate them. When the legs are unfolded, the table will appear as in Fig. 6, and be found handy if only for toilette purposes.

Our desk is now finished, and needs only to be stained and varnished or polished. In this, as in so many other details, the amateur must please himself. Personally I should prefer a dark walnut stain, French polished; but, once more, it is a question of taste. So, for that matter, is the whole style of the desk, which, but for facility of execution, might have been made otherwise.

But at least the amateur is now in possession of what the French call the "mother idea," and he can apply it as he thinks fit. I only trust that the results will be so satisfactory that no haunting sense of imperfections may disturb his dreams when he comes to lie on the desk-bedstead herein described.

## A FEW HINTS ON MAKING TAPS AND REAMERS.

BY DAMON.

Taps: how Made—Grooves—Shank—Finishing Hand Tap—Alteration in Hardening——Length—Number of Flutes--Their Shape—Cutting Flutes—Finishing Cut—Backing-off—Hardening—Tempering—Polishing—Making Reamers.

Although amateurs do not, as a rule, make their own taps and reamers, it sometimes happens that some special thread tap, or some particular size or taper of reamer, which one does not already possess, is required, when it is much quicker and cheaper to make it oneself instead of having one made by a specialist. A few hints on the usual method of manufacture may, therefore, be acceptable to novices. There is nothing new in what follows; but I am only writing for those who know nothing about the subject, and not for proficients.

Taps are generally made in sets of three. Fig. 1 shows the usual forms. Fig. 2 is a section to show the shape of the grooves or flutes. The dotted circle in Fig. 2 represents the bottom of the thread cut by the tap. The shank of the tap, marked *a* in Fig. 1, is turned down to rather less in diameter than the bottom of the thread, so that the tap may be passed right through a hole which has been tapped by it. This saves time which would be occupied in unscrewing the tap. The end of the shank is filed or shaped square to fit the tap-wrench which is used to turn it, if a hand-tap; or has a flat on it, or may be tapered to fit the chuck which holds it, if a machine tap. The thread is cut on a screw-cutting lathe in the usual way. Hand taps are usually finished off a trifle small (a very little), because hardening a tap makes it slightly thicker and shorter, so that it cuts a thread bigger in diameter than the tap was originally cut. Machine taps, however, are generally full, so that screws and bolts will be an easy fit. No definite rule can be given for allowances to be made for alteration in size during hardening, because different brands of steel vary so much.

Experiment with a piece of the steel being used is the only method of determining the amount. Then if the same brand of steel is always used, and the same process gone through in hardening, the same results may reasonably be expected, and the probable variation either in thickness or length allowed for. For all ordinary purposes, however, it does not matter, because the hole is tapped first, and then the screw is made to fit; and no amateur would attempt to make templet taps. Always use good steel for tap-making, and, in fact, for cutting tools generally. It does not pay to use poor stuff, for it will not take a good even temper, and, consequently, will not wear well.

There is no universal rule for the length of taps, but a proportion of about four times the diameter for the length of the threaded portion, and about four times for the length of the shank answers very well, and makes a nice-looking tap. It is better to adopt some system in making all kinds of small tools, so as to have the series uniform. Neglect of this principle is one of the great failings of amateurs and others who only occasionally make their own tools. The proportions given above are shown in Fig. 1, the diameter being taken as unity. The square on the end of the shank is usually made one diameter long.

The number of flutes is usually three, but in very large taps five may be cut, as it saves weakening the tap by cutting deep, and lessens the work on each cutting edge. An *odd* number, however, should always be used. If three flutes are cut, the width of the flute should be one-sixth the circumference of the tap, so that the width of the thread left is equal to the width of the flute. If five are put in, the width of the thread between them should still equal the width of the flutes. This is the proportion usually adopted, and is one easy to work to, and makes the taps look uniform; besides which, it provides plenty of room for the cuttings to lodge as the tap is screwed down: an important factor in the satisfactory working and length of life of a tap or reamer.

The shape of the flutes should be something after the style of those shown in Fig. 2, the corner, B, being well rounded. If a small corner is cut, as in Fig. 3, the tap is very likely to crack in hardening at the point B, and as soon as it comes to be used it will break. Some tap-makers cut the groove as shown at C, Fig. 3, but personally, I prefer Fig. 2, because the cutting face is radial, you get plenty of room for the cuttings without going deep with the flute, and one milling cutter will serve for fluting many different sizes of taps. Three cutters are all that are required for all sizes of taps—one to use from $\frac{1}{2}$ in. downwards, one from $\frac{5}{8}$ in. to 1 in., and a large one for $1\frac{1}{8}$ in. upwards. If the cutting angle of a tap is made too obtuse, and it is a large one, the force required to turn it round is very considerable; while, on the other hand, if it is too acute, although it cuts very freely, it soon gets the edge broken, and is spoiled. A radial face, and the thread only backed off a little, seems to be a good medium, especially for small taps. For large ones the angle may be made more acute, as the threads are stronger in proportion to the amount of metal they have to remove.

The flutes may be cut either in a shaping, milling, or slot-drilling machine, or, failing any of these, in the lathe by means of the slide-rest and overhead motion. This latter method is the one the amateur will most probably adopt. If it is intended to cut the flutes in the lathe, the tap must be fastened rigidly to the face-plate, so as to revolve with it. The ordinary driver will not do for this purpose, as it allows backlash. Fig. 4 shows the driver I generally use. An ordinary carrier is fastened on the shank of the tap. The end of the carrier passes between the two jaws marked *a*, *a*, one of which is tapped at A to receive a screw which holds the carrier fast against the other jaw. Of course an ordinary bell-chuck or jaw-chuck may be used; but I have found the above-mentioned driver so useful, that I consider it well worth the time spent in making it, as it can be used without taking off the face-plate, whereas a chuck cannot. There is one thing in making milling apparatus which should not be lost sight of—always make it strong enough. The action of a milling cutter tends to make the work spring and "chatter," which would effectually prevent a good finish being put on the work, besides, probably,

breaking some of the cutter teeth. To have a good appearance, the flutes should be cut the same length and depth. Nothing looks worse than irregularity in this respect. In fluting, it is best to work round the tap backwards—that is to say, having cut the flute marked *a*, Fig. 3, cut *b*, the one behind it, next; so that you can readily see when you have gone deep enough. If the flutes are cut in a lathe having no dividing-plate, three centre-dots may be made on the boss of the face-plate, so as to divide it into three equal parts, and one on the face of the head-stock as a pointer. The dots are then carefully brought opposite one another, the spindle locked, and the loose head-stock centre screwed up tight before cutting. Start the cutting at the point of the tap. The finishing cut should be a light one, to avoid springing the work as much as possible. The flutes having been cut, the next process is filing the "burrs" off. It will be noticed that a considerable "burr" is left on what will be the cutting face of the tap, spoiling the shape of the thread. This must be got rid of. By filing the face a little the "burr" may easily be broken off, using a chaser or anything of that kind for the purpose. On no account should the sides of the thread be touched with a file.

The threads will now require backing off to give them clearance. The taper tap will require the most clearance, the plug tap the least. The plug tap, in fact, has very little to do, being merely to ensure the holes being the same size and to cut a full thread at the bottom of a hole. There should be very little clearance from the circle, but a little is necessary. The next thing is to stamp on the diameter of the tap and number of threads per inch, with the maker's name, if thought requisite, as shown in Fig. 1. Squaring the end of the shank is also sometimes left till now. Reamers are generally stamped with the diameter, or the taper per foot if tapered.

The taps are now ready for hardening. This is by far the most difficult part of the job, owing to the uncertain behaviour of the steel. Before the steel is used at all it should be thoroughly softened by heating it to a dull red, and leaving in sawdust till cold. It is then much better to work, and is more likely to harden properly. One of the most annoying things in tap-making is to find a long tap or reamer, on which great trouble has been spent, bent or crooked after hardening, perhaps to such an extent as to render it useless. This is an occurrence which amateurs often experience. Annealing before using tends to lessen the danger, while much hammering increases it. If possible, therefore, a tap or reamer should be turned down to shape out of the solid, and not forged. If forging is necessary, the steel should be thoroughly annealed after it, then roughed out in the lathe and annealed again. Hammering sets up strains in the metal, which suddenly show themselves in hardening by causing the metal to bend. Roughing out even, if a heavy cut be taken, may cause strains, which may affect the satisfactory hardening. If the greatest accuracy of size and pitch is required in a tap, it is best to anneal after roughing out in all cases, whether the tap has been forged or not.

As to the proper heat for hardening, a deal depends on the particular brand of steel being used. Some steel will harden at a lower temperature than others, and the best heat is undoubtedly the lowest which will give the requisite degree of hardness. Experiment only will decide what this heat is. It is very little trouble to try a piece, and it may save a deal of time and money. Of course you have only the eye by which to judge the heat, and some practice is required to tell properly when two pieces of steel have been heated to about the same degree. Any way, steel must not be overheated, for *burnt* steel is undoubtedly *spoilt* steel. What smiths call "cherry red" is about right as a rule. In heating, the greatest care must be taken to heat evenly, and to prevent burning the thin cutting edges before the thicker part is properly hot. The fire should be clean and bright, but not too hot. It is a good thing when hardening taps or milling cutters to get them slightly red, and cover them with the ordinary mixture used for case-hardening, and then continue the heating. This has a tendency to prevent the cutting edges being burnt.

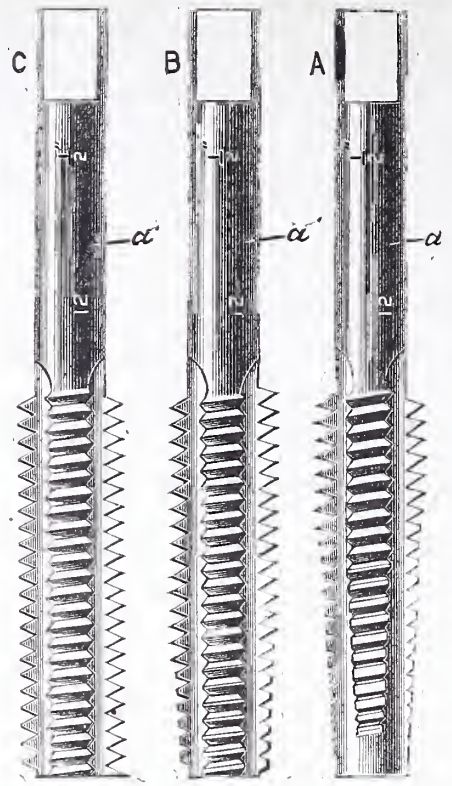

Fig. 1.—Taps of usual Form in Set of Three—A, Taper Tap; B, Tap; C, Plug Tap.

In spite of the quantity of different mixtures which are given as hardening medium, I prefer water. The ordinary cooling trough in the smithy will do as well as anything if the water is not greasy or too warm. Never try to harden a large tap in a small quantity of water. Always have the tank large enough, and plunge the tap steadily and quickly in, holding it meanwhile in a vertical position. If the tap is plunged in in an inclined position, it is nearly sure to be crooked.

When the hardening is accomplished the flutes must be brightened with emery-cloth. About half an inch of the shank nearest the thread should also be polished to show the colour while tempering.

Tempering should be done slowly. The slower the steel is heated the more uniform the temper is likely to be, and consequently the less likely are you to have the cutting edges too soft, while the rest of the metal is too hard: a frequent fault with novices, and one which is ruinous to the lasting qualities of the tool, as the edges wear away almost immediately it is used. If the temper is let down too low, the only thing is to re-harden and try again. A few failures must be expected at first, as some experience is required to tell when the temper is just right.

A good way of tempering taps, reamers, and tools of that class, when there are not many to do, is to get some pieces of tubing large enough to let the tap pass easily in. Get one of these pieces to a nice red heat, and then commence to heat the next, so that as you are using one and it cools, the next is getting ready. The tap should be oiled all over, and held with a pair of tongs in the hot tube, which may rest on a V block on the anvil. The tap must not be held still, but be moved about and turned round, keeping it meanwhile in the middle of the hot tube so as to temper it evenly. The colour must be carefully watched on the brightened parts until it reaches a "nut brown," or "dark straw" colour, when the tap must be rapidly cooled in water. These colours are rather difficult to describe, but by examining a new tap or milling cutter it is readily seen and should be carefully noted. If the tap is only intended to be used on brass, it may be left harder.

After tempering, the shank is polished

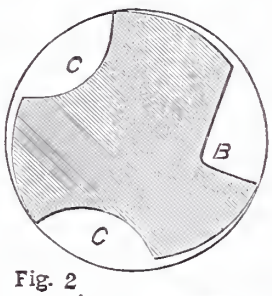

Fig. 2.

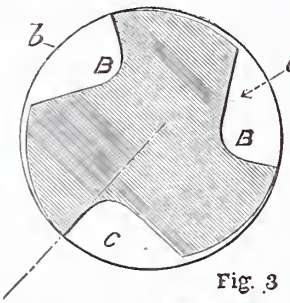

Fig. 3.

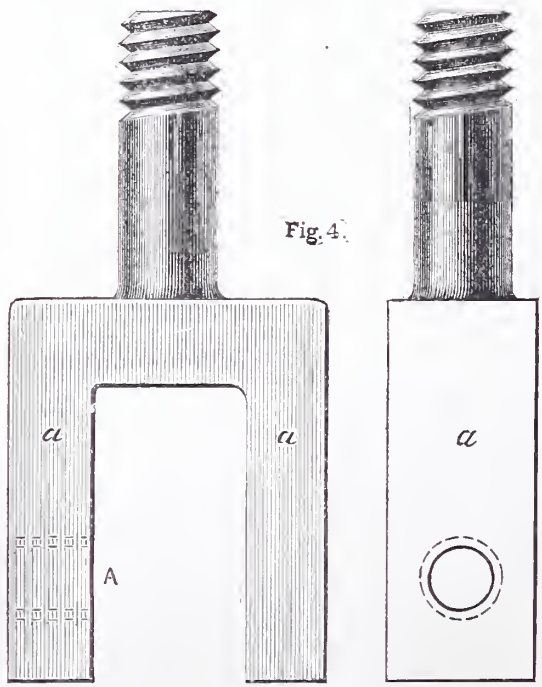

Fig. 4.

Fig. 2.—Section showing shape of Grooves or Flutes, with Cutting Faces Radial. Fig. 3.—Section with Corner Cut at B. Fig. 4.—Driver—A shows where Tapped for Screw.

in the lathe, leaving the colour on the flutes and about a quarter of an inch up the shank. The tap is then oiled all over, and is ready for use.

The method followed in making reamers is similar to that followed in making taps, In turning they are usually left full, and ground to templet size after hardening and tempering. If the reamer hardens a bit crooked it will often grind up to size. In fluting, cut a little deep, to allow for this grinding. More flutes are usually put in reamers than in taps ; an inch reamer may have nine, or even more, depending on the nature of the work to be done with it. A good pitch for the flutes is from $\frac{1}{4}$ in. to $\frac{5}{16}$ in. Always put in an *odd* number of flutes. If there are longitudinal grooves in the hole to be reamed, the flutes should be cut spirally. Reamers are somewhat given to "chattering." An irregular spacing of the flutes in a great measure obviates this, and should always, if possible, be adopted. The difference of spacing must only be slight, about ·0025 being quite sufficient. The cutting faces should be radial; the bearing surfaces should be narrow. In backing off, much clearance should not be given, but a little is necessary to allow the cuttings to get clear of the bearing surfaces, or they will make the hole rough. If too much clearance is given the chances of chattering are increased, which will cause the cutting edges to wear very fast, or perhaps break, and the reamer will be spoiled. For brass or gun-metal more clearance may be given than for iron, and the temper may be left quite hard.

In conclusion, I hope these few notes will make the paths of the novice in tap-making a little smoother. The hardening will be found to be the greatest difficulty ; the way in which a well-finished tap or reamer will bend or crack is most exasperating after some hours have been spent on it. Thoroughly annealing the steel before using, and leaving no sharp corners in the flutes, will do much to prevent these two evils.

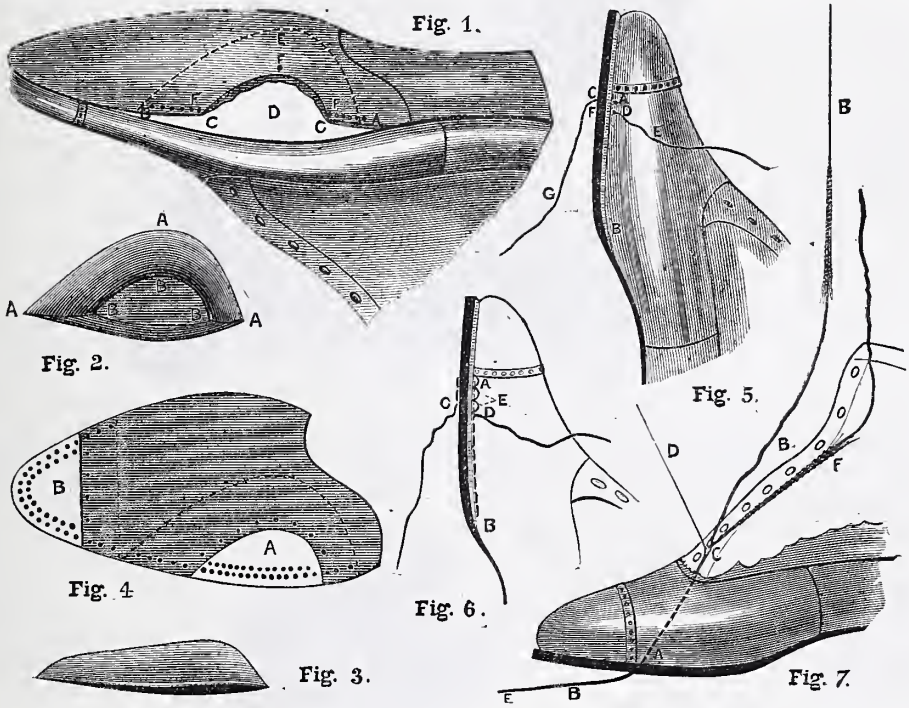

Fig. 1.—Section of Boot, with Sole Prised and Fitted to receive Underlay. Fig. 2.—Underlay, showing way to Fit and Skive it. Fig. 3.—A Skiver for Levelling. Fig. 4.—Half Sole, showing how to Underlay and Toepiece, and where Nails should be close to resist Wear. Fig. 5.—The Way to Loop-Stitch the Upper to the Sole. Fig. 6.—The way to make use of the Seat-Stitch in the forepart. Fig. 7.—The Way to Stitch-Draw, or a Substitute for Blind-Stabbing.

## BOOT AND SHOE REPAIRING.

BY W. GREENFIELD.

UNDERLAYING—TOE-PIECING — THE LOOP-STITCH—THE SEAT-STITCH—HOW TO STITCH-DRAW.

WE will now deal with the minor subjects in repairs that have connection with the sole, or bottom.

By underlaying is meant putting a piece under a sole where it is worn. Many people wear away the sole very quickly on the outside, while a few do just the same on the inside, and in either case an underlay in time will often save a sole.

When this kind of repairing is necessary most shoemakers (if they term themselves such) put the piece on outside—on top. This they do because it is less trouble, but I want you to spare no pains to do a small job well, because it is that alone that will make a large one come easy. Besides, anything that needs repairing is quite old enough. What it wants is to be made to look as much like new as possible.

To underlay, a last or iron foot must be put inside to keep the part that wants repairing quite solid. If the boot is machine or hand-sewn, rip it with a knife from A to B (Fig. 1), and lift it up as C C. If it is riveted it will have to be prised up with a chisel, and the rivets drawn out from A to C and B to C. Then cut out a piece of good sole leather, wetted, to the shape of Fig. 2; roughly skive it round the curved side, A A A, and then push it under the old leather at D (Fig. 1), but not quite as far as you know it will have to go ; then trim the old leather round from C to C with a knife, not taking off much, but all that is weak and thin, and being careful not to cut the new leather if you can help it. This done, knock the piece in to where it is wanted—that is, the dotted line E—and now draw a pencil mark round the curve you have cut, from C to C, on the new piece. Take the piece out again, and from the line B B and B scoop it out with the knife to A A and A, in the same way that you did the old in grafting a half sole, for in that case the old leather had to receive the new, and in this the new has to receive the old (C C, Fig. 1). Now put the piece in again, and put three short rivets in at F, F, F. Trim up the edge, leaving it quite full to allow for graving, rasping, etc.

If the boot is hand-sewn, then it must be sewn down from A to B, and it will look neater if a channel is cut in the new piece to receive the stitch, but as I shall have to give full particulars of this in another article, it will be out of place here, so it must be sewn through in the same way that the patch on the upper is sewn down. If it is riveted or machine sewn it can be riveted down from A to B, about the same distance from the edge, and in a like manner to that shown in half soling, in No. 112 of WORK, and in either case the edge can be knifed, pared, rasped, and finished as there described.

When a boot is worn very bad the underlay is not always enough to make the edge the proper substance ; then a little piece equal to what you want to fill that vacant place can be skived off a piece of hard sole leather, well wet, somewhat the shape of Fig. 3, put under the layer and riveted, or sewn down with it.

Toe-piecing. That is nearly a similar thing to underlaying, only it is at the toe ; but everything is fitted and done in the same way as shown by A and B (Fig. 4), which also shows how they should be nailed both on the old and new leather, and that it is often wise to put an underlay and toe-piece as well to a sole—more especially if the boot is old—as it saves a sole, and uses up the odd pieces of leather.

It sometimes happens that the upper leaves the sole for some distance along the side of the boot, say from A to B (Fig. 5). One way to sew this to the sole again is by loop-stitching it ; the loop, which is inside and draws the upper to the sole, can be set at every stitch, or each alternate one, but take care not to make the holes too large in the upper. To proceed, make a hole with the sewing awl through the sole from A to C, draw the thread through, and halve it ; then with a fine stab awl make a hole in the upper ; at A put the right hand end through, and draw it out through the inside of the boot ; make another hole at D and draw the end through to the outside, as shown by E. The hole is found inside, as shown in the last article on blind-stabbing ; though for such work as this it can be done another way, which I will show here, by the stitch-draw, later on.

When you are thus far, make another hole through the sole from D to F ; put the left end (C) in first, then the right (E), pull them tight on both sides, and the loop-stitch is set.

Another way is the seat-stitch. For this a row of rather long stitches are set in the upper, as from A to B (Fig. 6). This can be done with a stout stab awl and a sewing thread (about 9 cord of "Patent, No. 9"), with the stitches quite close to the sole. Then, at A, bore a hole through the sole, as A C (Fig. 5), being careful to make it exactly opposite the centre of the first stitch on the upper, A (Fig. 6) ; then lift up this stitch by putting the point of the sewing awl under. Then put one end through this stitch and the hole you have made in the sole, and halve thread as above. This leaves one end in the sole on the left and one through the

stitch on the right, as at C and D, only there are three stitches set to show how each stitch is caught up and drawn down; the two loops at E are only left loose to illustrate. Of course, each stitch must be pulled in quite tight, as it is that that draws the upper to the sole.

The stitch-draw is a ready means of finding the hole inside a boot, where it cannot be seen. We will take, for instance (Fig. 7), the fore part of a boot, and that you want to get a bristle through at A from the inside; well, B B B must be a spare end; it can be put through the hole A from the outside, and drawn nearly through; then, some little distance away from the bristle, say at C, a hole can be made with a fine awl; then take one end of the thread you are going to sew with and put the bristle D through the hole C, till you get to the junction of the bristle where the thread goes between, as shown at C; then pull the thread, B B B at E, back again until the bristle D F is through to the outside; take it out of B B B, hold it at D with the left hand, while B B B is pulled through with the right from the inside.

This, it will be seen, is blind-stabbing, with less learning. But when blind-stabbing is learnt it will prove, although this is very handy, it is blind-stabbing with less speed.

## OUR GUIDE TO GOOD THINGS.

*** Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of WORK for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of WORK without charge, the notices given partake in no way of the nature of advertisements.*

### 53.—Massey's Small Launch Engines.

I TAKE the opportunity afforded me in the present number of WORK to call the attention of my readers to the specialities of Mr. Henry B. Massey, Engineer and Machine Tool Maker, Spalding, Lincolnshire, a manufacturer of amateurs' lathes, planing and milling machines, etc., who is well known in the Eastern Counties. It is not for these only, however, that he is noted, as he is a maker, also, of steam launch engines, one of which, an entirely new design, is illustrated in Fig. 1. These engines are of improved construction, having double steam jacketed cylinders and valve boxes in one casting, supported, as may be seen, on six forged steel pillars, which tend to render the engine as light as possible, and also imparts great strength to it just where it is most needed. The outside of the steam jacket is lugged with mahogany, and fitted with polished brass bands, giving the engine a neat appearance. Each piston is fitted with three steel rings. The crank shaft is of a special combination of cast steel and iron, which renders it very tough and strong. The reversing handle can be either vertical or horizontal as may suit the convenience of customers. The main bearings, eccentric straps, guide plates, glands, etc., are of hard gun metal, and set up with double nuts. The smallest size has a bore of 2½ in. and 3 in. stroke, and is suitable for driving a boat about twenty-five feet long. The price of the engine is £30. The illustration in Fig. 1 is from a drawing of an engine with 5 in. cylinders and 5 in. stroke, the price of which is £55. Intermediate and larger sizes are supplied at proportionate prices.

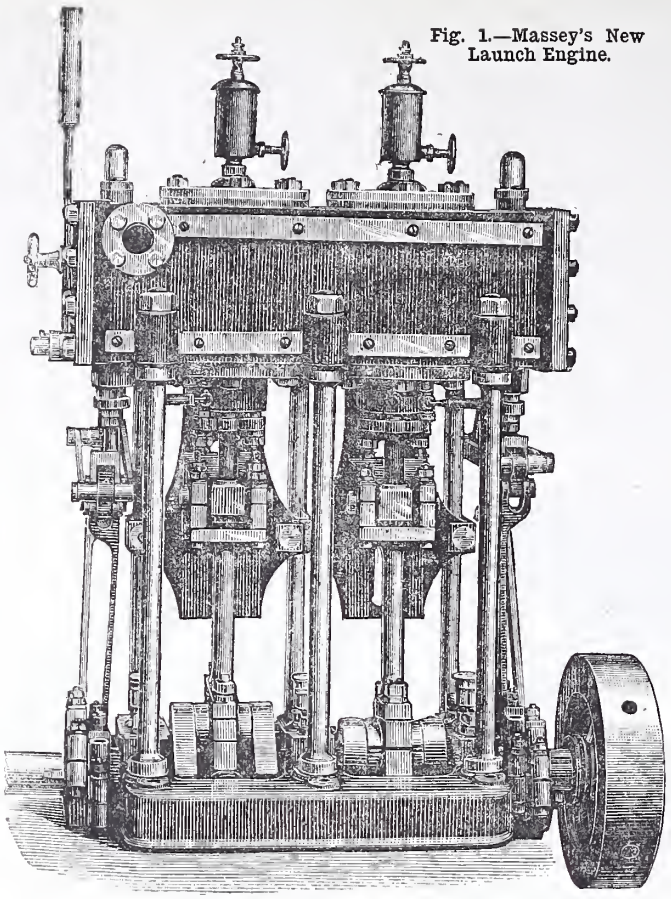

Fig. 1.—Massey's New Launch Engine.

### 54.—Massey's Improved Planing Machines.

These planing machines are manufactured in five sizes, the three smaller sizes being specially suitable for the requirements of amateur engineers and others who require, and are desirous of doing, small but good work. They are of sufficient strength to take good cuts off any sized piece of work that they are capable of taking in, and are provided with a self-acting feed motion in the horizontal cut. The fiddle slide is made specially strong for vertical cutting, and is graduated for angular work. The T-slots in the tables of all the machines are cut from the solid metal, and all heading screws are of steel. The two larger sizes are similar in design to the smaller ones, and suitable for the purposes of mechanics, electricians, and amateurs requiring to do a larger class of work. Nos. 1 and 1A machines are fitted on short standards for bench, and plane in length 14 in. and 18 in. respectively. They are sold—No. 1 at £12, and No. 1A at £15. No. 2 size, which is represented in Fig. 2, planes 24 in. long by 12 in. wide and 10 in. deep. This is a hand-power machine, and is sold at £20. Nos. 3 and 4 machines plane, the one 3 feet, and the other 4 feet in length, and are made to drive either by hand-power or by steam-power, or by both. The prices of these machines are £30 and £36 respectively. Various forms of vices and special chuckings for angle work are made to suit all sizes of machines. The construction of these machines are sufficiently apparent from the illustration that has been given of No. 2 size, and there will, in consequence, be no necessity for saying anything further with reference to its parts and action.

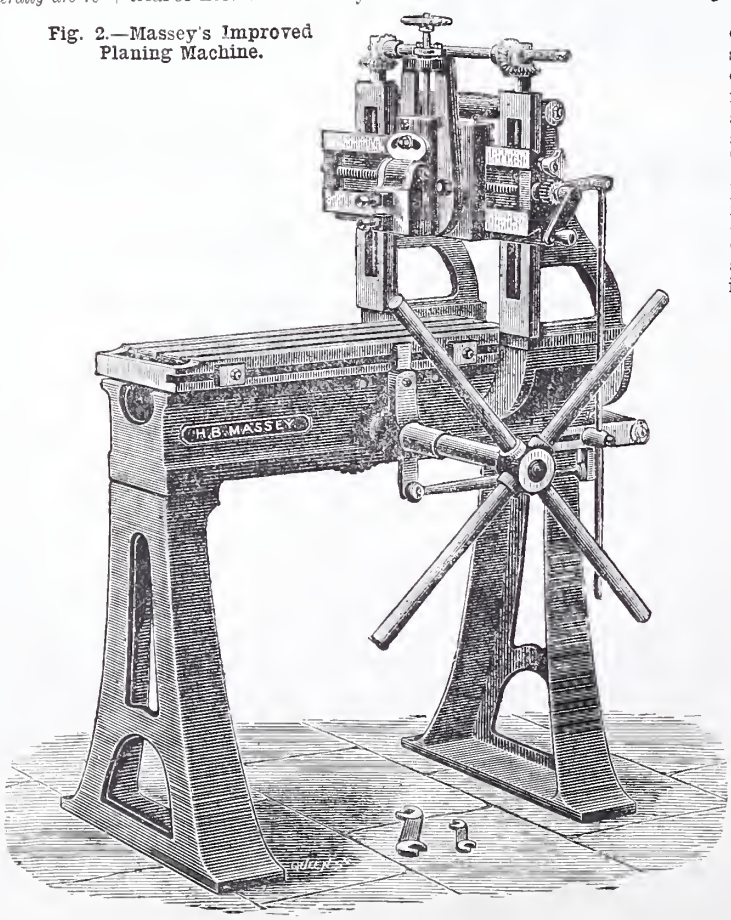

Fig. 2.—Massey's Improved Planing Machine.

### 55.—Watch and Clock Making.

Readers of WORK should not lose sight of the excellent series of scientific handbooks, entitled "Manuals of Technology," published by Messrs. Cassell & Company, Limited, and edited by Professor Ayrton, F.R.S., and R. Wormell, D.Sc., M.A. Neither professional clock and watch makers nor amateurs who like to try their hand at cleaning their own clocks should be without the manual. "Watch and Clock Making," written by Mr. David Glasgow, Vice-President of the British Horological Institute. It affords, first of all, a clear and succinct account of the progress of the watch and clock trade from the earliest time to the present day, and then proceeds to deal with the theory and practice of every branch of the art in an intelligible and exhaustive manner. For practical workmen it forms a most desirable book of reference.

THE EDITOR.

## JGGESTIONS FOR WORKERS AND HINTS TO INVENTORS.

A PERPETUAL CLOCK.—Mr. Justice Day has itten a letter praising a new device in clocks, invention, it is said, of a Leeds gentleman. claims that his clocks are driven solely by tural electricity from the earth itself. If this opens up an entirely new field for in-ntion, and, in effect, gives the world a new tor power. We cannot help thinking, how-er, that the vague description given of this w departure in horology scarcely conveys a ry clear description of what is actually accom-shed. An anode and cathode must, at all ents, be used, and one of these must sensibly teriorate within a limited period. But the ea is attractive and those having a taste that ay might profitably experiment. A sufficiently werful current once obtained, the mechanical rangement offers no difficulty whatever.

TYPE WRITERS.—Patent agents are often asked nat particular invention would be most likely prove profitable to the designer, and a ry common answer is a really cheap key-type riter. There are many machines in the market, ch as the "Merritt," "Columbia," &c., which int beautifully, but do not allow the user to tain the speed necessary for such work. The key riters hitherto produced are excellent machines, most every one of them possessing some dis-nctive feature, but the cheapest costs ten guineas. machine that would sell for two or, at most, ree, while retaining a key action, would pro-bly be the most profitable invention of its year.

ELECTRICAL PLANT GROWING.—Although the ggestion that the electric current would mate-ally hasten the growth of plants has been here id there followed up, nothing like concerted tion, under circumstances which would effec-vely preclude even unintentional deception, as yet been attempted. We might suggest to ur readers that they might render good ser-ce, both to science and horticulture, if they ranged to try the experiment in concert at me large market garden establishment, where mparison of the electric and non-electric ethods of cultivation could be publicly and curately tested. If the assertions occasionally ade are true, the former will, ere long, come to fashion, and will conduce to the material nefit of its users. An American journal gives the result of recent experiments by a cor-spondent a saving of one week out of five in using lettuce and similar plants. This would worth securing if the expense were not too reat, but upon this point no specific informa-on is to hand. Meanwhile, experiments nearer ome would be of interest.

AN EASILY MADE ÆOLIAN HARP.—One of the mplest and easiest ways of making an Æolian arp is to take a plain piece of common deal, bout an inch shorter than the window in which ie harp is to be fixed, and as wide as it may be esired to make it, dovetailing or mortising the ids into two channelled, round pieces of wood f the same width, so that the whole will loosely t the window frame. Elastic bands, or pieces f india-rubber cord, of varying thicknesses should ien be passed into the channels at the two ends, hich will thus keep three, five, or as many lastic cords as may be desired, stretched close to, ut not touching, the deal centre-board. This placed in the window frame, and the window rawn down when the arrangement is complete.

The channels in the cords may be of any de-ired depth, provided they keep the strings clear f the centre-board and of the bottom of the ish. Square or half-round pieces may be used or the ends, but to those possessing a lathe it ill be easier to make them circular, cutting the hannels at the same time; or a piece so turned ay be cut in half longitudinally and nailed or crewed to the centre-board ends. No very neat tting is required, and the harp when completed urnishes much amusement to children. Of ourse, the sound is somewhat different to that iven by a harp with metal strings, but it is not musical, and the elastic bands or cords are very ensitive to a current of air.

## SHOP:

### A CORNER FOR THOSE WHO WANT TO TALK IT.

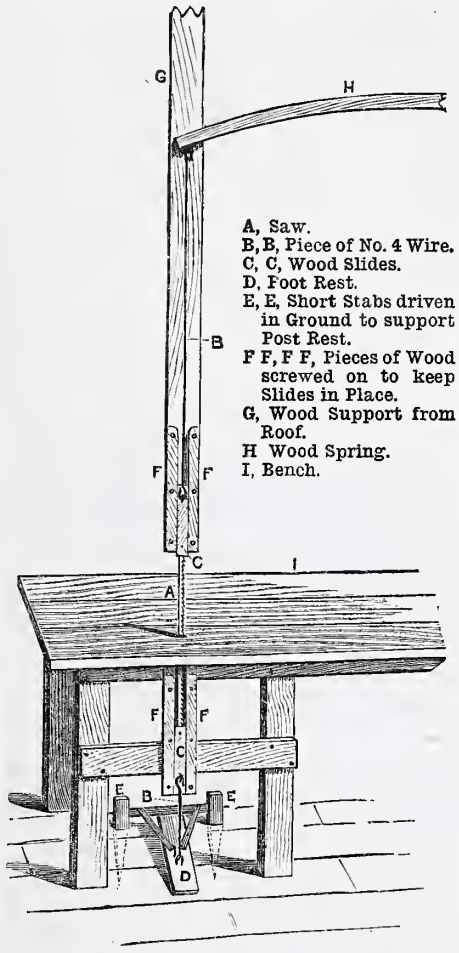
*** *In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—LETTERS FROM CORRESPONDENTS.

**Cotton Belting. — Erratum.** — J. N. (*York*) writes:—"In the answer to S. A. & Co. (*Stockport*), page 254, Vol. III., '56 feet' should read 5,656 feet per minute as the running rate of the cotton rope referred to."

**Saw.**—W. W. (*Caverton*) writes:—"I send herewith a sketch of a saw I have just put up, which I find works delightfully. It cuts 1½ in. stuff just like



Saw.

cheese, and I think it is the simplest saw that could be made. If there is anything that is not quite clear, I shall be glad to answer any questions about it in 'Shop.' C, C are slides kept in their places as a dovetail, and there is a weight of about two stones on the foot-board."

### II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**Gas Engine Slide Valves.** — JACK. — I don't think you can re-face the valve of your gas-engine unless you are an engine-fitter, and accustomed to the use of file and scraper. There must be four surfaces to get up, also the valve must be perfectly parallel. You would require a couple of files and a scraper, and a good surface-plate. It is not likely the valve would be cut deeply enough to require planing.—F. A. M.

**Developer.** — PHOTOGRAPHER. — The developer you refer to is Secretan's New White Developer for dry plates, lantern plates, Argentic bromide paper and opals, which can be used for either plates or paper without fear of fog or stain. For short exposures it is invaluable, and if diluted with an equal quantity of water, and more time given, will develop every detail without any tendency to hardness. For paper pictures the ordinary developer diluted with twice its bulk of water is most valuable. There is no fear of any stain, in fact, prints can be taken out of the developer and placed in hypo without washing, and no stain will occur; it is, however, advisable to wash in water before fixing. No acid water is needed. The ordinary developer gives great sparkle and delicacy in lantern slides and clear glass in shadows. In any case the developer can be used continuously for a number of exposures, thus avoiding the necessity of mixing fresh solution for each development.—D.

**Writing on Glass.**—J. S. (*Cardiff*).—For handbooks on this subject write for particulars and prices to The Decorative Art Journals Co., 15, St. Ann Street, Manchester, and to Messrs. Brodie and Middleton, Long Acre, London, W.C.—H. L. B.

**Price for Lettering Signs.** — SKIBO. — Find out what are the approximate charges that are ruling in your neighbourhood. Prices also depend upon the class of work required and the skill of the workman.—H. L. B.

**WORK Numbers, etc.**—E. G. (*Nottingham*).—There are fifty-two numbers in each yearly volume of WORK. Volume II. began with No. 53, and ended with No. 104. The price of back numbers is one penny. All the back numbers can be had of the publishers, Cassell & Co., Limited, Ludgate Hill, London, E.C.

**WORK Volumes and Contents.** — W. C. (*London, E.*).—The price of the volume of WORK is 7s. 6d. through any bookseller. The Indexes to Volumes I. and I. and II. are published at one penny each.

**Chamfer Plane.**—Y. R. (*Middlesboro'*).—I have not seen a plane like yours, and think it would not work well. The cutter, fixed as you show, would penetrate too deeply at first, and its fixing would give way. Better get a plane maker to get out a plane suitable for the purpose. The fault in yours is that there is no wood or other material fitting the curved surface, and limiting the penetration of the cutting edge.—B. A. B.

**To Strop a Razor.**—RAZOR.—The two articles mentioned by you were written by different people, so that the terms used by one would not necessarily be employed by the other. In the article "How to Strop a Razor," I make no mention of the term "lines of friction," but you are wrong when you say these cross one another in that article. Note the lines on razor in Fig. 5 in article "Setting a Razor":—"They are slightly inclined from the handle and back towards the point and cutting edge." These lines should have been rather more inclined to agree with the position of razor on the stone (Figs. 1 and 2); but as they are only to illustrate what the meaning of open and crossed lines are, they answer the purpose very well. If you will now turn to the article "How to Strop a Razor" (see No. 105, page 7), and note the position of razor, A, Fig. 1, and imagine the path it takes while descending to D, Fig. 2, the lines of friction *on the razor* will take the same direction as those recommended in article "Setting a Razor" (see No. 100, page 782): that is, inclined from the handle and back towards the point and cutting edge. On reversal, B, Fig. 1, is drawn upwards till it assumes position C, Fig. 2; again, the lines of friction are from the handle and back towards the point and cutting edge. The only crossings of the line of friction I can see is that, on the upward stroke of the razor, it crosses at an angle on the strop the path which the razor formed on the downward stroke. This is the only case in which the lines do cross. If in "Setting a Razor" (Figs. 1 and 2) the tool were held at right angles to the stone and pushed forward, and at the same at an angle across it, and always worked in the same angle, the same effect would be obtained as by holding it at an angle and pushing it straight forward, as advised. I, in stropping a razor, proceed by the former of these methods: that is, hold the razor almost square across the strop while drawing it upwards and sideways, or reversed. I hope you will be able to follow these few notes.—P. B. H.

**Improved Bottle.**—LONG VALLEY.—So far as we can gather from the particulars sent us, we fail to see any novelty in the plan proposed, inasmuch as we used just such an arrangement over thirty-five years ago, and found it very convenient, as it possessed all the benefits and advantages proposed in the description. The words suggested as a title for a trade mark would not be registered, as they would be held to be "descriptive" not "distinctive," which the law and ruling of the courts hold no valid trade mark may be. If a trade mark is obtained as a separate property from the patent, the right conferred thereby becomes the property of the public directly the patent right expires. An inventor may, of course, prepare his own title, specification and claims, and put them in himself, and in many cases will do better by this than in seeking the aid of an "agent," who, in too many cases, is incapable of affording an inventor any useful aid in obtaining a sound and valid patent, as far too many are merely copying clerks, law writers, amateur dabblers, and otherwise unqualified and unable to afford what is essential for obtaining of a sound patent, or, otherwise, a legal property; in either case he would not secure what he seeks, and is supposed to desire, when he decides on applying for the grant of a patent. An inventor under such circumstances is in the position of the captain of a

ship, with no chart on board, seeking to enter a strange port on a dark night without the aid of a properly skilled pilot to take him in, and about as likely to sueceed. There is no difficulty in any one getting a patent granted in response to his application, but then, if it is not a valid one, capable of securing the support of the law to sustain it, what good is it? There is not a day that passes that at least half a dozen useless, imperfeet, and invalid patents are not applied for, and if put in, in accordance with the rules as to the size of the paper, etc., are granted to the applicants, but until they have passed the ordeal of the law courts are not a decided property.—C.E.

**Water-proof Cloth.**—A.M.—(*Conndon*).—We have never heard of the material named being applied to the purpose mentioned. What we have always seen used in the interior has been pitch, which, so far as we know, fully answers the purpose required. We have inquired of various persons who are engaged in the business here in London, but they, none of them, ever heard of it being so used. There is a eheap material employed for covering the exterior which may be had of Messrs. Dottridge Brothers, Dorset Works, East Road, London, N., who supply all that is necessary and required in the business, and if A. M. will send his trade card and inquiries, we have no doubt they will furnish him with all particulars, prices. etc.—C. E.

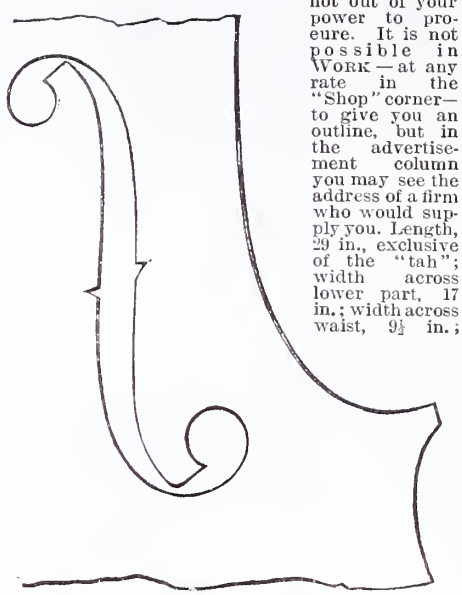
**Trade Marks.**—LONG VALLEY will, doubtless, have seen that his former letter has been answered in due course, hefore this can appear.—C. C. C.

**Engine Cover.**—W. (*Hough, near Grantham*).—Sailcloth makers produce a special matcrial for this purpose called "tarpaulin canvas," which is well suited for the object in view, and moderate in priee, being very strong. To make it, measure the length of the engine with the funnel lowered, over all down to the lowest point it is desired to cover, and do the same over the breadth of the engine. This will give the area of the cover, *i.e.*, length by breadth. This canvas is, we believe, woven in breadths of twenty inches wide; therefore, to ascertain how much will be required, turn the number of feet into inches and divide them by twenty, the resnlt will be the numher of hreadths needed to give the width, and the length in feet multiplied by the number of breadths, and, divided by three, will give the number of yards required. The canvas must then be sewed together with a "sailmaker's seam," using untarred sail twine, and the edges may he doubled in and stitched so as to form a broadish hem, or be roped round after scwing on a rope or line of the size selected. Now spread the cover out on a boarded floor, and taek it down at the four corners to keep it steady and even. If it be desired to make it a "tarpaulin" cover, get some Stockholm or vegetable tar—taking care *not* to use coal or gas tar—make it boiling hot, taking great care that it *does not boil over*, or there may be a job for the nearest fire brigade, and when it has got thoroughly heated it is then fit for use. Whilst this is being done, under the charge of someone to keep it stirred and lift it off when it seems likely to boil over, you should, with a whitewash hrush and a bucket of water, brush the canvas all over—taking care to do it evenly—letting it absorb a good dose of water, and then with a long-handled tar brush apply the hot tar evenly and liberally all over it, and it will be found that as the water evaporates, the tar will dry into the canvas and be absorbed into its very substanee. In a couple of days' time, if the weather is dry and hot, you may give it a second dressing of hot tar—this time omitting the water—and, when dry, it is fit for use, unless it be preferred to give it a third coat hefore using, which will be beneficial. In case the tar may be objected to the cover may be waterproofed in the following manner. Take 1lh. soft soap, 1 gallon hoiling water, 3lbs. mixed paint of any desired colour, mix them well together and coat the canvas evenly all over with it. When dry it may be finished off with one or two coats of oil paint of the colour it is desired to remain. We have used both these plans and found them satisfactory. Of course, a greater quantity of this waterproofing may be made at a time by increasing the quantity of the materials named, hut keeping to the proportions specified.—C. E.

**Photography.**—A. W. (*Paisley*).—You slightly misconceive the purpose and intention of these columns, which are for the express purpose of giving short and concise replies to correspondents. A. W.'s case is not at all uncommon. We should advise that *working* models be made of each instrument, and then, *if* they bear out the expectations of the maker, he should then obtain the provisional protection of the Patent Office, and afterwards submit them for approval to any good manufacturing firm and make his own terms with them. We may remark that rough sketches, such as those sent, give very little idea of the *real working* capabilities of the completed instrument, and we must decline to offer an opinion as to the practical value of the inventions. Plans and diagrams are all very well as suggestions in working out a design, but utterly differ from those carefully made from the completed work. Very few will be found not to require considerable modification hefore they realise the intentions of the designer.—D.

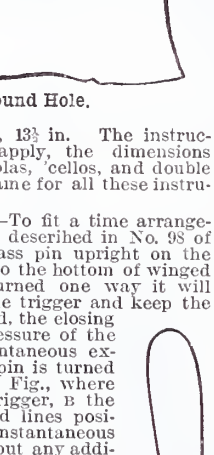
**Effective Pressure Rivet.**—BILSTON.—The mean effective pressure of the steam is hest obtained by taking indicator cards from both ends of the engine cylinder, drawing a series of equidistant *breadths* of the diagram perpendicular to the atmospheric or line of pressure, adding them together, and dividing the total by the number of the divisions. This will give the effective mean pressure per square inch through the stroke, or rather, one revolution. The effeetive energy exerted by the steam on the piston during each double stroke or revolution, is the product of the mean effective pressure, the area of the piston, and the length of the stroke, or (p.m-p.m.) A.S., and if N be the number of double strokes in a minute, the I.H.P. in foot pounds per minute is (p.m.-p. m.) A.N.S., from which the indieated horse power is found by dividing hy 33,000. The net or effective horse power is ohtained by the use of the formula :—$\left\{\frac{P}{r}\left(1+\log\frac{r}{2}\right)\text{-p b}\right\}=\text{A.L.N.}\frac{}{33,000}$.—C.E.

**Violoncello.**—J. D. (*Glasgow*).—Herewith you have a good pattern for sound-hole. I have previously replied to your query (*re* Bass Bar). The following dimensions may perhaps assist you, hut you ought to have a good outline. This is surely not out of your power to proeure. It is not possible in WORK—at any rate in the "Shop" corner—to give you an outline, but in the advertisement column you may see the address of a firm who would supply you. Length, 29 in., exclusive of the "tah"; width across lower part, 17 in.; width across waist, 9½ in.; width across upper part, 13⅜ in. The instructions in violin making apply, the dimensions of course excepted, to violas, 'cellos, and double basses: the rules are the same for all these instruments.—B.



Violoncello Sound Hole.

**Blind Shutter.**—NERO.—To fit a time arrangement to the blind shutter deserihed in No. 98 of WORK, solder a small brass pin upright on the trigger; rivet another pin to the hottom of winged nut, so that when it is turned one way it will engage with the pin on the trigger and keep the lens open as long as wished, the closing being done by a second pressure of the trigger. When only instantaneous exposures are required the pin is turned out of the way. Sce the Fig., where A represents the pin on trigger, B the pin on nut, and the dotted lines position when turned for instantaneous work. Another plan, without any additions to the shutter, would be to carefully wind the shutter until the lens is fully open, then close in the usual way. Hope I have made it plain; hut if any further difficulty, write again.—W. E. D., JR.



Shutter Time Arrangement.

**Brooms.**—BRUSHER.—Numerous plans have been brought forward for the purpose named, and some have been patented, but whether they have been adopted or turned out useful we do not know. We should not advise any attempt at patenting before the novelty of the invention has been ascertained, as it would most probably turn out that the idea had been puhlished or used before. If there is a free public library in the town, most probably eopies of the specifications will be found there. If not, the Patent Office will present a set if application is made for the same in a proper manner. Failing this the hest thing would be to spend a few hours in the Patent Office Library, Southampton Buildings, Chancery Lane, London, and consult the specifications bearing on the matter, when BRUSHER may quickly ascertain if there is any novelty in his plan.—C. E.

**Xylonite.**—G. A. B. (*Normanton*).—The address is:—The British Xylonite Company, Limited, 124, High Street, Homerton, E.

**Spots on Sword-Scabbard, etc.**—TROOPER.—The sword scabhard being of iron or soft steel tarnishes more readily than the sword blade, and requires protecting from rust. To remove rust stain and preserve from reeurrence of such to any of the iron or steel appointments, adopt the following plans. Sword scabhards are apt to get rusty inside as well as out, and communieate stains to a sword blade. Unscrew the small nut-screw that holds the lip edge in the top of the scabbard, take it out, also the thin pieces of wood or leather which line the scabbard; elean out any rust with long thin blades of iron on which is tied emery eloth; then rub paraffin oil, replace the wood or leather casings the same way they were drawn out, and screw the lip in its place again. For outside spots or stains, rub them with fine emery powder and lard, using the end of a cork or soft pieee of willow. When all the stain is got out, apply rotten-stone or tripoli and sweet oil on these parts—this is to smooth the dulness caused by the emery powder—then go over the seabbard with this rotten-stone with a soft woollen rag; this will equalise the lustre all over. Finish off with a soft wash leather or a soft piece of old silk rag with whiting, or charcoal powder, free from oil; the blade to he brightened in the same way. If much rusted all over, adopt the following plan. First cleanse from grease—should any be there—with a hot solution of soda, and wipe dry. Then make up with 1 pint of hydrochlorie (muriatic) acid to 1 quart of water. Let the articles to be cleaned soak twenty-four hours, scrub the rusty metal well with a hrush till the parts are bright, or nearly so, eomplete the brightening of the patchy places with fine emery and lard—after you have thoroughly washed off all the acid, which must not be allowed to remain on. The scahhard, sword or stirrups will have a dull, lustreless surface through the action of the acid, or "pickle," as it is termed by workmen. Now use emery and lard. After the emery brightening use the rotten-stone and oil, finishing as before deseribed. Many things are used for surface protection, and are sold by cycle dealers. To make your own, any of the following serve. Have a box of dry slaek lime, and keep bits, spurs, stirrups and chains in it; they will not rust there. A sword best kept in a green baize bag, and ruhbed up now and then. If kept in an armoury or hung up hand for use or display, cover with mercurial ointment or equal parts of carholic acid and sweet oil rubbed on with a rag, or one part of paraffin and two parts of mutton suet smeared over. Plumbago and lard are a good cover; a better is dry white lead and lard—this must be warmed to be removed. As a rule, troopers after their drill see to their appointments, and do not let water stains remain on the but clean off at the first chance. Five minutes then save an hour's work or more that neglect will cause. The hurnisher and burnishing chalk are essential to get up lustre to steel or iron. If want of a hurnisher, use a large new bradawl or any round hright steel tool. If mustered in the rain, a light rub of sweet oil hardly dims the lustre of steel, and preserves from rust.—J. C. K.

**Bicycle "Hub Dish."**—SELF-HELPER.—The "hub dish" your correspondent means the steel cup in the hub end where the balls run. A new cup would have to be sweated in by using a medium sized blowpipe, which would not injure the plating. The new cup must be heated up sufficiently to temper hard by sudden cooling in water. Small quantities of steel castings can be had of George's Cycle Company, Upper Street, Islington, or Brown Bros., 7, Great Eastern Street, London. They will give castings for their own patterns or machines, or make castings from patterns sent.—A. S. P.

**Conservatory.**—BOTANY.—The construction of a small conservatory of the dimensions you give, viz., 17 ft. by 5 ft. wide—is a very simple matter, and the work may he readily undertaken by an amateur of ordinary ability. You would do well to set out the dimensions on paper to a scale, say half an inch to the foot; then with a pair of compasses and a rule you can ensure the centreing of every pieee of timber the required size before putting together. Having regard to the possibility of the glass-house being required to he removed, it would be hetter to leave out the hrick-work, and construct the house of wood and glass only. It should make a ground frame of wood, 5 in. wide by 1½ in. deep, the ends of which may he plain overlapping joints; to the corners of this frame should he neatly fitted the four uprights, of 4 in. square each, which should be kept in a vertieal position by means of struts, eight in number; then four lengths of the 4 in. square stuff should he fitted crosswise to the uprights to form the top frame. Prepare a ridge-board, 1 in. thick hy 6 in. wide, to which the rafters must be fitted and connected to the top frame. These rafters, or sash-hars, may be purchased ready-cut to the required shape in every town almost. Of course, some of the same matcrial must be used for the side lights, and the spaee helow must be conveniently covered inside and out with matched boarding; the space being filled up with sawdust, which is a bad conductor of heat. The most suitable kind of wood for the framework is dry spruce deal, as free from knots as possible; and, unless you are a good amateur wood-worker, it will be best to buy the door or doors ready-made; certainly it will be cheaper. For artificial heat hot water is the best, and the system most reliable in a small way is to have jacket-boiler and stove combined, costing from about £2 10s. upwards. This will hold a good supply of coke, and will require very little attention. If further details are required write again.—C. M. W.

[M]**agnetic or Galvanic Belts.** — J. McA. ([Gl]*asgow*).—The belts and appliances for the cure [of r]heumatism and paralysis, made and sold by Mr. [Col]e, 248, Caledonian Road, London, N., are made [o]f permanent magnets. Similar appliances may [be m]ade of 3 in. lengths of hard crinoline steel per[ma]nently magnetised, coated with silk, and sewn between two pieces of fine flannel. If made up [in t]he form of a belt, quilt the pieces of magnetised [stee]l at distances of two inches apart, vertically, in [two] rows throughout the length of the belt. The [tw]o ends of the belt may be fastened with leather [stra]ps and buckles, or with straps made of webbing. [The]re need be no difficulty about making the belts. [Mr]. Cole's success is due to his knowledge of how [to a]pply the magnets, for, if wrongly applied, they [wil]l, he claims, do more harm than good. Lumbago [is a] rheumatic affection of the lumbar muscles. A [ma]gnetic belt worn around the loins should give [rel]ief, and aid other measures (hygienic and [die]tetic) in effecting a cure.—G. E. B.

[M]**anganese.**—Oblong.—Manganese is a metal of [a r]eddish-white colour, obtained from ores found [in] Cornwall, Devonshire, North Wales, Somerset, [Wa]rwickshire, Aberdeenshire, Wicklow, Germany, [Spa]in, Austria, Italy, France, Sweden, Canada, and [th]e United States of America. The ores vary in [com]position, but that found in most abundance is a [per]oxide of manganese, composed of one part [ma]nganese and two parts oxygen, represented by [th]e chemical formula $MnO_2$. This is the ore em[plo]yed, when broken to the size of peas, to charge [th]e porous cells of a Leclanché battery. When [us]ed in this way it will last just as long as it has [an]y free oxygen to part with, the time being [go]verned by the quantity of the ore placed in the [cel]l and the quantity of electricity drawn from it in [tha]t time. If a Leclanché battery is frequently [us]ed for long runs of more than ten minutes at a [ti]me, or if the battery is connected to work having [a] low resistance, or short-circuited by connecting [th]e two terminals with a short thick wire, all the [ox]ygen available from the manganese will soon be [us]ed, and the cell will be soon exhausted.—G. E. B.

[E]**lectric Light for Necktie.**—Long Reader. [U]nless you are a working jeweller, knowing [so]mething about electric appliances, I should not [ad]vise you to attempt making an electric light [sc]arf-pin for the necktie. The tiny pea-lamp used [in] making these pins cannot be made outside a [su]itable workshop, fitted with costly machinery. [Th]is class of jewellery can be obtained from [M]essrs. J. E. Hartley & Co., 13, St. Paul's Square, [Bi]rmingham, or from Messrs. Cathcart & Peto, [5]8, Hatton Garden, London, W.C., who also supply [th]e small ebonite batteries for furnishing current [to] the lamps. One of these batteries, containing [tw]o cells, will go easily into the inside breast pocket [of] a coat and light up a 4-volt lamp.—G. E. B.

[S]**hip Stoker Engineer.** — Sahab. — If your [co]rrespondent will refer to the Merchant Shipping [A]ct Amendment Act, 1862, he will find it is [sp]*ecially* provided that "service in the capacity of [s]eaman, stoker, donkeyman, greaser, winchman, [la]bourer, engineer's steward, or any other capacity [th]an that of engineer taking watch on engines and [bo]ilers for propelling, will not be accepted." The [ob]ject of this Act is to provide that only properly [qu]alified men should have charge of the machinery [on] board ship, which is now of such a powerful and [co]mplicated character, and requires men of com[pe]tence and ability to have charge of it. The ser[vi]ces of mere "drivers" and "cock turners" are of [no] utility in the present day, as the circumstances [an]d conditions of steam-ship machinery have so [en]tirely changed. It is a most wholesome and ne[ce]ssary provision, in the interests of the public who [ha]ve to travel in them, that the machinery of such [sh]ips should be in charge of only properly qualified [an]d competent men, as life and property are so [em]inently dependent on their skill, ability, and [at]tention. Unless our correspondent has served [hi]s time at making and repairing engines, "he [m]ust prove that for not less than three years he [ha]s been employed as a journeyman mechanic in [an] engine factory or workshop on the making or repair[in]g of engines. In either case he must also have [se]rved one year at sea in the engine-room as an [en]gineer on regular watch in the foreign, home, or [co]asting trade, or he must have served at least four [ye]ars at sea in the engine-room as an engineer on [re]gular watch in the foreign, home, or coasting [tr]ade." Having done all this, he may offer himself [fo]r examination, and on the results of this examina[ti]on will depend whether he can obtain a certificate [en]titling him to be employed as a capable man in [th]e engine-room of a steam-ship. For each grade [of] engineer, the candidate must prove by examina[ti]on that he is a fit and proper person to be en[tr]usted with the care of engines and boilers on [re]gular watch at sea; and if he cannot do this, he [w]ill not be certified as fit and proper to fulfil the [d]uties required, and, consequently, must be content [w]ith what he can obtain as fireman, donkeyman, [g]reaser, etc., as provided by the Act.—C. E.

**Bicycle Papers.** — One Anxious. — The ap[p]earance of my article rests entirely with the [E]ditor of Work, who has the full series of papers [o]n Safety Bicycle Construction in his hands.—[A]. S. P.

**Cleaning Oil Paintings.** — No better man can [b]e recommended than Edwin W. Izod, 220, Great [P]ortland Street, W.—F. B.

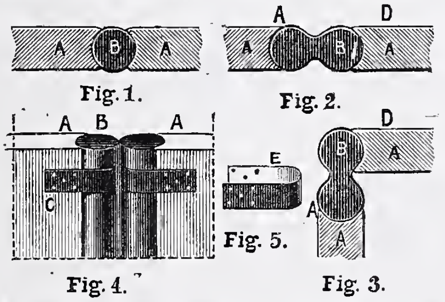
**Framing Oil Paintings, etc.** — A very good [a]nd reasonable man is Wm. Hayward, 18, Giltspur [S]treet, E.C.—F. B.

**Scroll for Iron Kitchen Stand.**—T. H. (*Newcastle, Staffs.*).—Had you sent a sketch, however rough, of your stand, it would have given me a better idea of its style; as it is, I have done my best, bearing in mind the materials to be used, and trust it may suit you. I have added the "T. H." to fill up the centre space. You will remove all the

Scroll for Kitchen Fender.

white shown in the design, and if you prefer plain Roman letters, you may substitute them for those given. One word of caution: the centres of the two O's will require small stays being left, or they will drop out.—Worker Bee.

**Screen to Fold without Exhibiting Crevice.** — H. C. (*Lee, S.E.*). — The method you illustrate (which you observed in a farm-house) of constructing a screen in such a manner that it shall show no crevice between the frames is a very good one; but it was some time before I clearly understood all your sketches, and was in doubt as to what use the clamps were. However, it is overcome, and I reproduce your drawings, shaded, and with necessary additions. First, however, I must tell readers that, constructed as in Fig. 1, it will not fold flat, which you explain; but that, as in Fig. 2, all will be well as regards the folding. I cannot really see the advantages gained, as the amount of extra labour necessary, besides the appearance of the clamps, will hardly be compensated for. An ordinary screen, with towel-horse joint, and covered completely with fabric, pleated where it contacts with the union of the frames, should not be objectionable. If a screen of the sort with joints (Fig. 2) were covered completely with fabric, the latter would, as in ordinary cases, have to be pleated, for the distance from A to D (when partly



**Screen to fold without exhibiting Crevices. Fig. 1.—Plan of Screen (which will not fold flat). Fig. 2.—Plan of Screen to fold quite flat. Fig. 3.— Ditto with Frames at Right Angles to each other. Fig. 4. Perspective View of Fig. 3. Fig. 5.—Clamps to retain Frames to Rod.**

folded) would be in excess of that from A to D (open). At any rate, I will explain your letter. B (Fig. 1) is a rod extending the whole height of the screen, to which fits the grooved edges of the frames, A, A. Two or more clamps (C) are screwed to each frame in such a way that they show on both sides of the screen, while the bend (E) passes around the rod B, which should be slightly shallowed to receive them at those parts, thus retaining the frames. With screen, Fig. 1, they must be fixed one above the other, while with Fig. 2 both on a level; in the latter case the bends passing through slots. The upright rod of Fig. 2 must consist of a shaped solid piece, or of two rods screwed together. Had you shown a *perspective* sketch, however roughly, of clamps, I should be more readily have understood.—J. S.

**Wood Sample.**—T. A. (*St. Helens*).—The sample of wood sent is American white wood, and can be purchased at any yard in Liverpool. The price would be about 3d. per foot super.—A. J. H.

**Drill Chuck Slipping.**—Bertie.—I think it will comfort you to know that the slipping of your drill chuck has probably saved the life of some of your drills, which would otherwise have been broken off; so it is not an entirely bad feature. You don't say what sort of chuck you have, so I will suppose it is one of those you clasp on the drill by turning it with the hand. I have an old one of this sort which takes drills up to ½ in., and have frequently found it slip when holding the larger sizes, and have had to stop and close it harder, when it would generally hold unless the drill caught, as it does sometimes when just getting through a hole; that is, when drills are most often broken, unless the chuck slips. But suppose the chuck slips when you are simply boring, then you should consider how you can reduce the strain on it. Does the drill want sharpening? of course it will take double the power to drive if it is blunt. Are you, perhaps, trying to bore too large a hole out of the solid? Say you want to bore a ½ in. hole, you should use about three drills in succession, say $\frac{3}{16}$ in., ⅜ in., ½ in., if you are boring in iron. If it is brass you are boring, another difficulty arises from the twist drill being too greedy for that metal, so that if the centre of the hole is cleared out it is apt to dig in. I should use a ¼ in. drill first, and then, in following with the ½ in. one, be very careful to hold the work *back* against the back centre, so that it cannot feed in too fast, as it is apt to do. The straight-flute drills are better for brass than twist drills.—F. A. M.

**Stain for Red Ivory Balls.**—W. C. R. (*Glasgow*).—Make your red dye as follows:—½ lb. of new scarlet cloth cuttings; rub in well ½ lb. of soft soap. Put in an earthen vessel, pour in two quarts of water. Boil for a considerable time, stirring occasionally, till the colour is extracted from the cloth. Take out the cloth, wringing it to get the whole of the dye out. Now dip your ivory balls into aquafortis, and then into cold water. Have the dye liquor just at the boil, then put in your balls without keeping up the boiling. The stain will strike in in a short time. Avoid any metal, as iron or copper, touching the balls, or it may make a dark stain on them. When taken out of the liquor, cover with a cloth so as not to dry too quickly. Another plan for red stain is to make up nitrate of tin thus:—Dissolve in rather strong nitric acid thin strips of metallic tin. Great care is necessary to add only very small portions of the tin to the acid gradually. This must be done in an earthenware bowl. Boil the balls in this liquor for a brief time, and then in cochineal dye, into which put some of the nitrate of tin. Let the balls boil till they assume the proper colour. You may buy the nitrate "bowl liquor," as it is termed, of a dyer who makes it. It may be as well to try the operation first on any old bit of ivory before trying on your balls. Let the balls be covered up with a cloth in drying, or they may crack on the surface.—J. C. K.

**Greenhouse.**—A New Reader.—You will find a thorough description of what you want in Nos. 12, 14 and 15, Vol. I., under the heading of "The Tenant's Greenhouse," where the subject is gone into far more fully than would be possible in the already over-crowded columns of "Shop."—E.D.

**Address Wanted.**—J. M. K. (*Glasgow*).—You have omitted to send your full name and address for A. S. P.

**Die Sinking.**—I. W. A. W. (*Wroxesbury*).—I may say that I am unacquainted with the process of Die Sinking and using, except that I know that making stampings for cycles is done with ponderous machinery, the steam hammer holding a prominent place. The dies are costly things to make, and, when made, unless many thousands of the parts are stamped from the dies, they will not pay the original cost. If I. W. A. W. wishes to become acquainted with this kind of work, he should get into a factory where such work is done, for there only can any useful experience be obtained.—A. S. P.

**Bicycle Castings.**—J. B. (*Glasgow*).—This correspondent can have my address of our Editor. I have the wood patterns of the parts referred to by him, which I can either lend or sell him; or I could get castings from them, but not in less time than one month. I get my malleable castings from Forsyth & Millar, Broad Street, Bridgeton, Glasgow.—A. S. P.

**Bicycle Tyres.**—Artist Novice.—Make a clean cut slanting, say, two inches long on both ends of the tyre with a sharp knife dipped in water; smear the cuts with Snell and Brown's "Tyre Splicing Solution"—of any cycle depot, 1s. bottles; let stand before joining an hour or so; then join the ends evenly and press together, the tyre may then be put on the wheel at once.—A. S. P.

**Cyclometer.** — Oblong. — Unless your correspondent is an optician, or perhaps a practical clock or watch maker, he could not construct a reliable cyclometer. Even then he would have to get a good one and dissect it, in order to see the construction; then he might make a copy. For any one unacquainted with that kind of work to attempt one would be simply out of the question. They can be bought very cheap, from 15s. to 30s.—A. S. P.

**Magic Lantern.**—H. E. (*West Bromwich*).—Before much assistance can be rendered to you, you must quote the article, number and page of Work to which your letter refers, and state specifically what you wish to know about.

**Cast Steel Wheels.**—Vulcan.—Do you mean the common wheels for pitch chains? If so, I should say the teeth should not be less than ⅜ in. broad by $\frac{3}{16}$ in. thick.—I.

**Sand Blast Machines.**—Toxtethian.—Except that the sand is driven against the files by a steam pressure of from sixty to a hundred pounds per square inch, I know nothing of the process. Still, if you hunt up the number of the patent specification, which you can do in the Liverpool Library; you can get a copy of it for a few pence of H. Reader Lack, Patent Office, Southampton Buildings, London, W.C.—I.

**Protractor.**—W. E. H.—I presume you allude to the instrument called the "protractor," which you can get of any mathematical instrument maker. What kind of "metal goods" do you want? Unless you say what class of goods you want, of course I cannot tell you where to go.—I.

**Model Engine.**—LEMUR.—Without seeing your model I cannot tell you what is at fault, but should think, from your description, that some portions of the mechanism are not sufficiently sensitive. Try the effect of easing some of the joints of the fittings.—I.

**White Enamel.**—F. L. (*West Cowes*).—The best job for a counter top would he to give it a solid coating of hest white lead paint, say four coats. Use the colour finely strained, avoid streakiness of brushwork, and use fine glass paper hetween each coat. Finish with two or three coats of white hard hath varnish, or one coat of any good maker's enamel. There are many other methods, but the above is usually the most practicahle. Don't attempt to make either varnish or enamel.—F. P.

**Repainting Wooden Boxes.**—J. T. B. (*Warrington*).—First get a little weak soda water, and cleanse and ruh down the surfaces with pumice stone, well rinsing with water at the finish. The inside and outside can now have a coat of thin cream paint, made with more turps than oil. Then stop all holes, etc., with putty. Now paint insides only a good oily coat of light huff, and then, next day, a coat of flatting paint a few tints lighter than hefore. Next, "ground" the outsides with huff paint, then comh them with graining colour, and varnish with "church oak." For graining, see No. 58, page 86; and No. 62, page 152, or the whole "Art of Graining," contained in Vol. II.—F. P.

**Damp-proof Paper.**—C. G. M. SOUTHARD.—I know of no arbitrary reason why either tar-paper —or the more modern and superior waterproof paper, made hy Stather & Sons, of Hull—should he fixed to the wall by either the coated or clean side. I see many pieces fixed in a twelvemonth, and the hulk of it has the coated side outwards. So far as experience and practice go, either side will affix itself hy stout paste to a wall in fair condition. In numherless cases I have had ocular demonstration of this fact, and, furthermore, I know of no *theory* for or against on either side. Sometimes, when covering it with a light and delicately tinted wall-paper, it is *advisable* to put the darkest side next the wall to prevent the hlackness interfering with the solidity of the flank of wall. If you use much of this article, send to Stather's for their patent paper, it is greatly superior to the old thing.—F. P.

**Articles on Plain Painting.**—G. M., JUNR. (*Portland*).—These articles, which appeared in Vol. I., consist of "Introduction," No. 27, page 418; "White, Yellow and Red Pigments," No. 29, page 450; "Blue and Black Pigments," No. 35, page 550; "The Three Simple Divisions of Colour—Secondary and Tertiary Pigments," No. 36, page 566; "Oils, Varnishes, and other Vehicles; Solid and Liquid Driers," No. 42, page 659, and continued in No. 43, "Mixing Oil Paints, and Compounding Tints and Shades of Colours for Practical Use," No. 44, page 698. In No. 46, page 723, the same subject is continued, and the second and third coating is explained. The final coating and flatting processes are explained on page 739, No. 47. These three papers last mentioncd contain a practical lesson on the actual manipulation, as well as much invaluahle matter respecting technique and theories. No. 50 contains an exhaustive paper on *tempera* work—"distempers." The concluding chapter is an illustrated one, on "House-painters' Brushes, Knives, etc." The best advice I can give you is to get the complete volume and have it bound up.—LONDON DECORATOR.

**Lime-Washing Walls.**—E. W. (*Chingford*).—The painter's apprentice usually does the liming work, and he also gets in a "fearful mess." The rougher the wall, of course the more it splashes. A very common brush also makes matters worse, as the cheap fibre will not hold the lime-wash like hristles, but the latter are expensive. I can only say get a dccent brush, and practice for a week or two to gain expertness! Use it fresh slacked, or it will not bind.—F. P.

**Material for Gilding On.**—REDCLIFFE.—Your query is scarcely explicit enough, but assuming you want a recipe for preparing the picture-frame makers' *composition*, with which the ornament is moulded, see reply to AMATEUR, page 683, No. 94, Vol. II.—F. P.

**Concertina Reeds.**—G. D. O. (*No Address*).—All these are made of hrass, steel, and German silver. The strips of metal of the proper gauge and temper to produce approximately the sound required, may he obtained from Messrs. Dawkins, Charterhouse Street, London, E.C.; hut they must be tuned hy filing in order to make them quite true as to pitch.—G.

**Photo Lithography.**—HALF-TONE.—Please accept my apologies in the delay in replying to your query, regarding the transfer of photos in half tone to stone, but I have heen ill with the influenza and unahle to write. There are several methods of doing this, one of which is to wash the transfer paper with the medium first, then photo on to this, and transfer to stone in the ordinary way; hut, with the Editor's kind permission, I will write more fully upon the subject as soon as ever I am well enough. Will W. G. BLACKBURN and LITHO (*Birmingham*) kindly accept the same apologies for delaying their replies.—A. J. A.

**Phonograph.**—T. H. (*Bradford*).—I am sorry I cannct give instructions for making these wax cylinders, for reasons that have been already given in this column.—W. D.

III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Gum.**—STICKY writes:—"Will any reader tell me through 'Shop how to make and put on gum sueh as is on the hacks of stamps and adhesive lahels?"

**Soap.**—G. A. (*Fulham*) writes:—"Can any reader inform me how to mako soap similar to the '*Sunlight*,' and whether it can he suhjected to any special treatment so as to strip and cut about an hour after it is put in the frames, even while it is still warm?'

**Colouring New Ivory.**—R. P. C. (*Sunderland*) writes:—"I would like to know the hest way to colour new ivory for piano-keys to match the old ones, which are of a yellow cast."

**Split Cane.**—J. T. (*Shadwell, E.*) writes:—"Will any reader kindly inform me as to the price, etc., and where I can ohtain cane ready split similar to that used in caning chairs?"

**Wood Pulp.**—C. H. C. (*Hornsey*) would he glad if anyone could tell him where pulp (wood preferred) is to be obtained.

**Pair-Oared Boat.**—H. C. (*Lancaster*) writes:—"Will some reader of WORK kindly give me a few instructions as to how to make a pair-oared boat, to hold about three or four persons? What kind of wood, etc., will he required?"

IV.—QUESTION ANSWERED BY A CORRESPONDENT.

**Fret Clock Design.**—M. (*Bishop Auckland*) writes in reply to H. O. H. (*Bristol*) (see page 222, Vol. III.):—"Try Booth Brothers, Upper Stephen Street, Duhlin; Harger Brothers, Settle, Yorks; J. H. Skinner and Co., East Dereham, Norfolk, or H. Zilles & Co., Wilson Street, Finshury, London."

**Crystoleum Painting.**—M. (*Bishop Auckland*) writes in reply to PAINT BRUSH (see page 238, Vol. III.):—"I have found starch a very suitahle medium for this purpose. You must use the best quality of starch."

**Artists' Easel.**—M. (*Bishop Auckland*) writes, in reply to S. A. W. (*Wallasey*) (see page 158, Vol. III.):—"I send sketch of one I made, which I think will suit you. Fig. 1 is the front view of the top joint, and Fig. 2 a side view. It is made in two pieces, the back one heing 2 in. longer than the front. The front is hollowed to receive the ends of legs, which are fixed with countersunk-headed screws. A notch is cut in the hack for the hack leg, which is fixed with a strong wire. The legs are jointed in the middle, as shown in Figs. 3 and 4, and turn upwards when folded. They are jointed with screws, and fixed open by a pin, as shown at A. The legs are 1½ in. wide and ¾ in. thick. A piece of brass, about the size of a foot-rule, is fixed

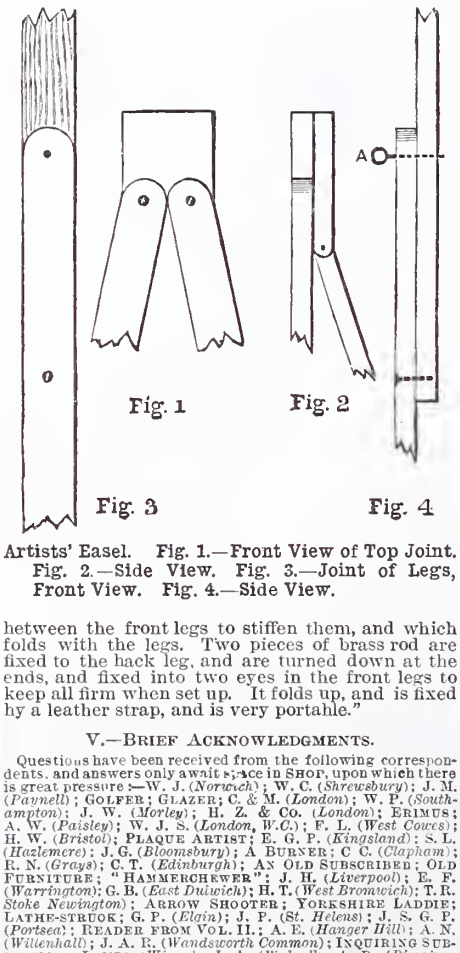


Fig. 1 Fig. 2

Fig. 3 Fig. 4

Artists' Easel. Fig. 1.—Front View of Top Joint. Fig. 2.—Side View. Fig. 3.—Joint of Legs, Front View. Fig. 4.—Side View.

hetween the front legs to stiffen them, and which folds with the legs. Two pieces of brass rod are fixed to the hack leg, and are turned down at the ends, and fixed into two eyes in the front legs to keep all firm when set up. It folds up, and is fixed hy a leather strap, and is very portahle."

V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only awnit space in SHOP, upon which there is great pressure:—W. J. (*Norwich*); W. C. (*Shrewsbury*); J. M. (*Paynell*); GOLFER; GLAZER; C. & M. (*London*); W. P. (*Southampton*); J. W. (*Morley*); H. Z. & Co. (*London*); ERIMUS; A. W. (*Paisley*); W. J. S. (*London, W.C.*); F. L. (*West Cowes*); H. W. (*Bristol*); PLAQUE ARTIST; E. G. P. (*Kingsland*); S. L. (*Hazlemere*); J. G. (*Bloomsbury*); A BURNER; C C. (*Clapham*); R. N. (*Grays*); C. T. ## AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their Improved Eclipse Cameras and Outfits, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.;** or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.;** securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra.

These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.,** post free.

*A Wholesale Dealer's Stock-in-Trade at about Half-Price.*

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

**J. H. SKINNER & CO., Manufacturers, W Department, EAST DEREHAM.**

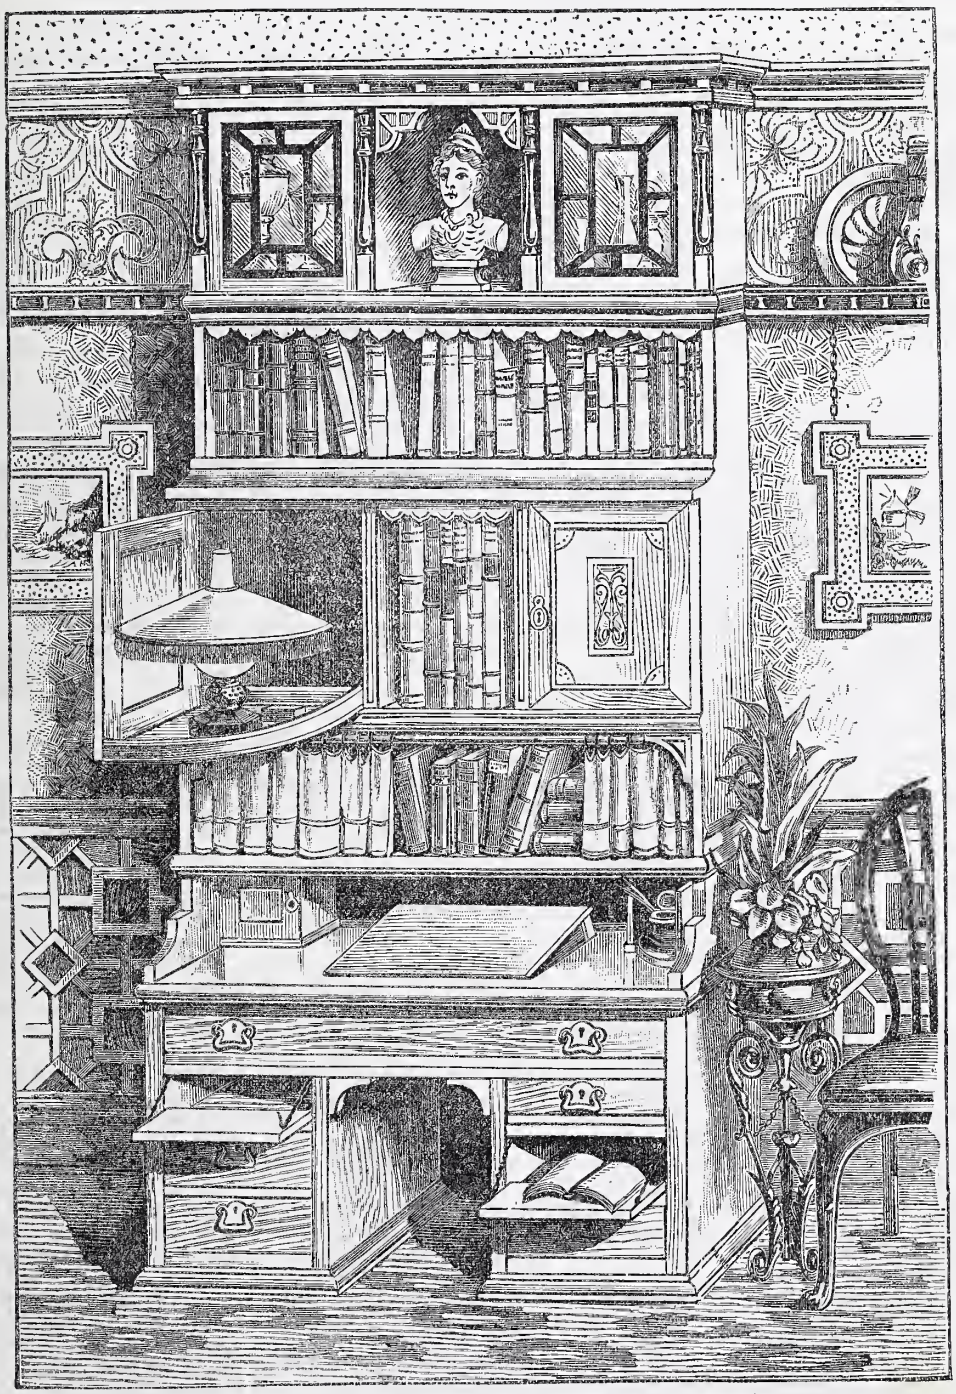
### DESIGN FOR WRITING-TABLE AND BOOKCASE.

BY MISS FLORENCE M. GARDINER.

It having been my lot, while staying in expensively and otherwise well-furnished houses, to suffer such physical and mental torture, owing to the inadequate and often total absence of some simple and compact arrangement for holding books and writing materials, that in self-defence I have been compelled to evolve a piece of furniture for this purpose, of which the accompanying design will give a fair idea. I feel sure it would be a welcome addition to most households, as it is well adapted to the requirements of every-day life; could be obtained at a moderate price, and would, doubtless; be within the capabilities of numerous amateur readers of WORK, with clever fingers and a taste for cabinet-making.

Though it is the lot of only a few to add to their income by the pen, yet everyone has more or less writing to do, and it is a priceless boon to have one's books (those companions of prosperous and evil days, and soothers of our idle hours) close at hand, instead of—as they often are—difficult of access when we most require them. Happily, there are few of us in this enlightened nineteenth century, with "souls so dead" that we have no favourite authors to whom, from time to time, we may turn for amusement, guidance, and comfort.

Here, then, is a design of a useful and handsome piece of furniture, appropriate to almost any room. Where the cost need not be considered, mahogany, walnut, or satinwood may be employed in its construction; but if it is necessary to practise economy, I would suggest deal, simply stained or enamelled in some suitable shade. In the latter alternative, I can personally recommend the excellent Foo-chow enamel paints of Messrs. Macpherson & Co., Knott Mill, Manchester, owing to their quick drying qualities, and the large range of colours to select from. In either case, brass fittings for the drawers should be used. The dimensions must, of course, depend upon individual convenience; but if one of the recesses found on either side of the fireplace in many rooms is utilised for this piece of furniture, the width would then regulate the size.



A Writing Table, Bookshelves, and Cupboards in Combination.

The table contains six small drawers and one large one. The fronts of the former fold down, and are firmly secured, thus serving the double purpose of library steps or shelves. The long one is divided into different compartments to suit the various kinds of paper, postal wrappers, telegraphic forms, etc., which are constantly needed, and so should always be close at hand. Under the sloping flap, space is left for placing letters and papers uncompleted. If desired, greater privacy could be secured by the addition of a revolving flap, which would entirely cover

the top of the table, when not in use; but as the object has been to minimise the cost as far as possible, this is not shown in the illustration.

The two small cupboards are respectively for the inkstand and pens, stamps, etc. The larger ones hold a lamp and different supplies, such as paste, gum, and the ink bottle.

The lower shelf is concealed by a curtain of plush, or other appropriate material, attached by rings to a brass rod. This forms a convenient receptacle for the various small articles which accumulate around one—for instance, pen and paper-knives, scissors, twine, rulers, etc. The central compartment and the shelf above are for books of reference; and the upper portion is divided into china cabinets with glazed doors. There is a niche between for bust, bronze, or any suitable ornament.

## ENGINE AND BOILER MANAGEMENT.

BY M. POWIS BALE, M.INST.M.E., A.M.INST.C.E.,

*Author of "A Handbook for Steam Users," "Wood-working Machinery," "Stone-working Machinery," "Pumps and Pumping," etc.*

### Rules for Engine Drivers and Boiler Attendants.

Steam Boiler Feeding—Incrustation in Steam Boilers—Fire Bars Warping, etc.—Condensed Steam in Pipes—Priming of Steam Boilers—Plugging Leaky Tubes—Drawing Tubes—Grinding in Cocks—Firing Steam Boilers.

I shall now continue my remarks on this subject and complete them in another paper. It may be as well to say that Rules 1-18 were dealt with in page 229 (*et seq.*) and Rules 19-30 in page 290.

31. *Steam Boiler Feeding.*—In working steam boilers, a certain and constant supply of water is of very great importance. It should be as hot as can be forced into the boiler. In small powers the pump may be attached to and worked by the engine, but with large powers we prefer to have a separate pump of simple construction, such as the donkey pump, as, should the engine break down, a supply of water may still be kept up in the boilers. If a plunger pump is used, care must be taken that the plunger is a tight fit; if it is worn, the pump may be working without forcing any water into the boiler, and should this not be detected, dangerously low water may be the result. Pumps for boiler feeding are best run at a moderate rate of speed—say, a plunger speed of about 300 feet per minute. Several successful automatic self-feeding water supply apparatus are also now in use. If feed-water is drawn directly from a river, a strainer should in all cases be employed, as dirt or sand may be drawn into the pump and disable it. In large establishments, and to avoid the chance of being laid idle, in addition to the pump it is advisable to have a second feeder; for this purpose an injector may be used. The chief advantages of using an injector are that it may be worked without running the steam-engine, and the steam admitted to the injector is condensed and re-enters the boiler, and from the absence of working parts the wear and tear is less than with a donkey pump. Injectors, however, should be carefully managed, or they may give some trouble.

In working injectors, which may be fixed horizontally or vertically, a continuous supply of dry steam is necessary. This should be regulated by a valve on the boiler or steam-pipe. The water supply must be continuous, and should not be hotter than 135 deg. Fahr. with low pressure, or 105 deg. Fahr. with the highest pressures. Injectors may be fixed either above or below the water supply, and they will draw from two feet to twelve feet, according to size. An injector has one advantage over a pump—that is, it will usually stop forcing water before the pressure in a boiler becomes dangerous, owing to a jambed safety-valve or what not, whilst a pump will go on forcing water and raising the pressure till the boiler has to give way unless the valve is released. An injector will not work if allowed to get hot or any dirt to get in it; the suction-pipe should in all cases be fitted with a nozzle. Suction and delivery pipes should be kept as free from bends as possible, as the friction of the water through the pipes is considerably increased by them.

Injectors, like pumps, must be kept very clean, and all pipes and joints perfectly tight, or they will not work. It is advisable to fit injector and pump pipes with cocks for draining off waste water; these will be found particularly useful in case of frost. For automatically regulating the water supply to about one level in the boiler—an important factor in economical working—several plans have been introduced; one of the simplest with which we are acquainted consists in the arrangement of a small single-acting steam cylinder mounted on the feed-chest, and having the piston-rod connected to the feed-valve, which is kept closed by the downward pressure of a spring on the steam piston. A pipe connected to the cylinder leads to the steam space of the boiler; the lower end of this pipe is closed by a valve, the spindle of which is connected to a counterbalanced lever having a float suspended from one end. When the float sinks below a certain point, the steam-valve opens and admits steam under the piston, which, being forced up, admits water into the boiler till the normal level is attained.

Sandy water should not be used as a feed-water, as it will rapidly cut the pump plunger to pieces and jamb the valves.

32. *Incrustation in Steam Boilers.*—Dr. Joseph Rogers, of Indiana, who has studied closely the question of incrustation in steam boilers, gives tannate of soda the preference over any other preparation with which he is acquainted for the chemical purification of the feed-water, and it is without doubt the principal ingredient of many of the boiler-cleansing fluids sold, about which the vendors profess to make a great secret. The action of tannate of soda may be described as follows: The tannates of lime and magnesia are insoluble in water; hence when tannate of soda is present the carbonates of lime and magnesia in the feed-water (and held in solution therein by the carbonic acid in the water) are precipitated as they enter the boiler in the form of tannates of lime and magnesia. These compounds are not crystalline, pulverulent, and heavy like the carbonates, but light, flocculent, and amorphous, so that they do not subside in the boiler, but are held in suspension in the circulating water, gradually finding their way to the mud collected, from which they can be blown out as may be convenient. The soda of the decomposed tannate of soda appropriates the carbonic acid of the lime and magnesia, forming a bicarbonate of soda, which in turn decomposes the troublesome sulphate of lime, forming sulphate of soda, which remains in solution, while the carbonate of lime formed is decomposed, as above stated, into tannate by fresh portions of the tannate of soda present. The solvent action of the tannate upon hardened scale is slow, but when the boiler is once clear there is little doubt that it is a most excellent preventive, and, unlike other remedies used, it has no injurious effect upon the iron of the boiler.

Numerous other remedies have been used to prevent incrustation, with varying success. Some of these we give herewith, but it must be understood we do not in any way guarantee their success. (1) Potatoes, $\frac{1}{50}$ of weight of water, is said to prevent adherence of scale. (2) 12 parts salt, $2\frac{1}{2}$ caustic soda, $\frac{1}{4}$ extract of oak bark, $\frac{1}{2}$ potash. (3) Pieces of oak-wood suspended in boiler and renewed monthly. (4) 2 oz. muriate of ammonia in boiler twice a week. (5) A coating 3 parts of blacklead, 18 tallow, applied hot to the inside of the boiler every few weeks. (6) 12 lb. of molasses fed into an 8 horse-power boiler at intervals is said to have prevented incrustation for six months. (7) Mahogany or oak sawdust in small quantities. Use this with caution, as the tannic acid attracts iron. (8) Carbonate of soda. (9) Slippery elm bark. (10) Chloride of tin. (11) Spent tanner's bark. (12) Frequent blowing off.

Hard feed-water containing lime, etc., may be softened to a very considerable degree by treating it with a mixture of lime and soda, allowing the precipitate to settle before the water is used. This will largely prevent incrustation.

33. *Fire-bars Warping, etc.*—One of the reasons for grate-bars warping is insufficiency of air space between the bars; this should be arranged to suit the fuel burnt, as some coal requires much more air space than others. Another reason is that in many boilers the fire-bar bearers are fitted close up to the bridge and head-plate, consequently hot ashes and clinkers accumulate, having no place to escape. This may be obviated by putting the bearers a short distance from the end of the bars, so that the ashes, etc., have room to escape into the pit. Long fire-bars warp more than short ones, and thick bars more than thin ones. The air spaces between the bars should be wider at the bottom of the bar than at the top, as this facilitates the admission of air and the escape of ashes. Air and water bars have their advocates, and doubtless possess some advantages; but the water-bar, although long known, has made little progress, probably owing to the cost of maintenance and the danger arising should they burn out or rupture suddenly. In burning anthracite coal, water hearths are used to some extent. A very great variety of fire-bars have been introduced, but I cannot discuss their merits or demerits here; it will be sufficient to say that good fire-bars should give ample air space, so that the amount of oxygen necessary for complete combustion is readily distributed through the fire, and at the same time should not be given to warp, and should be easily cleaned or renewed.

34. *Condensed Steam in Pipes, etc.*—There are two ways of effectively getting rid of this—viz., by using a steam trap for getting rid of the water after it is made, or by the use of a steam separator, which acts directly on the steam itself and relieves it of the water. To prevent radiation and reduce the amount of condensation to a minimum, all steam-pipes should in the first place be carefully covered with some good non-conducting composition, such as silicate cotton, slag wool, or asbestos. If the engine is situated more than 25 ft. from the boiler, it will be advis-

ble to fix a steam trap or separator in the pipe. Choose a simple form of trap; a good one is arranged with a cam motion for quick opening, combined with a loose valve, which reduces the friction considerably and renders it less liable to stick. We have recently seen a new form of separator in use which appears to give capital results. It consists, briefly, of a circular cast-iron chamber with a branch connecting it to, and forming part of, the main steam-pipe. The steam on entering the chamber is conducted to one side by a partition narrowed down at its orifice, so that in rushing in it acquires a whirlwind motion at a high velocity. The particles of water being of greater specific gravity than the vapour, are thrown outwards and run down the sides of the chamber, whilst the steam at the centre of the vortex, free from water, passes to the engine cylinder through a centre pipe provided for the purpose. This pipe is of trumpet form. The condensed water collects at the bottom of the chamber, and is released by a drain-cock. Expansion steam-traps should be used with caution.

Stop and starting valves should in all cases be turned off or on gradually, in the first case not to stop the flow of steam suddenly and cause a recoil, and in the second to allow the pipes to warm and gradually expand. We have known many cases of fracture from steam being suddenly turned into cold pipes. All steam-pipes should have as few joints and elbows as possible; the pipe carrying the exhaust steam away should be of ample size; small exhaust-pipes cause back pressure on the piston, and consequent loss of power. The beats or pulsations made by the escape of the exhaust steam should be at regular intervals; if they are intermittent or irregular, steam is probably passing the piston or slide-valve, which should be examined and adjusted. In conecting feed and steam pipes, allowance should in all cases be made for expansion.

35. *Priming of Steam Boilers.*—Priming or "foaming," or, in other words, the production of "wet" steam, may generally be said to arise from one of the following causes:—(1) Want of steam space; (2) too much water in the boiler; (3) dirty feed-water; (4) bad circulation of water or badly-proportioned boiler; (5) grease in the boiler, and some kinds of boiler fluids, especially if put in in quantities, will cause priming; (6) too much steam drawn from the boiler, causing a whirling motion on the water; (7) by forcing the fire. The amount of priming varies considerably with different boilers, and is to some extent under the control of the attendant. Perforated pipes or baffle-plates will usually check priming to a certain extent, and a wooden grating, fastened by chains, and allowed to float on the water immediately under where the steam is drawn from the boiler, will usually stop priming almost entirely.

36. *Plugging Leaky Tubes.*—Split or leaky tubes may be plugged for temporary use with iron or wooden plugs. Care should be taken that the plugs are not too tight a fit, or the evil may be increased in driving. In using wooden plugs, unless the split is a short one and at the extreme end of the tube, it is a good plan to use two plugs, driving one in past the split and another to follow it. Iron plugs, with a collar on the one end to close the end of the tube, are also used. Small leaks at the tube ends may often be stopped by expanding the tube with an expander, but care must be taken that this operation is not carried too far, or the tube may be split. Many boiler-makers prefer to plug tubes with well-fitted ferrules. The author has used the following plan with success, and can recommend it. Make taper plugs of pine about 4 in. long, bore a hole through them, and drive them in flush with the end of the tube. Take a round rod or bar of wrought-iron, and screw a thread on each end; pass the bar through the plugs, and put on saucer-shaped washers filled with red lead, to cover each end of the tube; put on nuts and tighten up. If tubes are plugged under steam, damp down the fire with small coal, and close the dampers.

Leaky feed-pipes, etc., may usually be temporarily repaired by wrapping them tightly round with narrow bands of canvas coated with white lead. The bands should be, say, 3 in. wide, and overlap each other half way; they should be very tightly tied on with waxed or tarred rope. Soft pine wood is the best to use for plugs, as the water penetrates the pores of the wood, causing it to swell, and the plug is thus held firmly in position. Oatmeal or any similar substance should not be introduced in a boiler to stop leaks, as they clog the water-gauge passages and valve-seats, which may result in serious accident; at the same time, they are liable to cause priming.

37. *Drawing Tubes.*—If the proper appliances are not to hand, drawing tubes is often a troublesome job, from accumulation scale of and other causes; but as a competent engine driver should be able to draw a tube, I give a note thereon. If the scale on the tubes is very hard, it may be cracked off by putting a red-hot bar into each tube before drawing. In the first place, cut off or bend in the ends of the tube, then pass a rod—arranged with an eye at one end, and a nut and strong steel washer at the other—through the tube; if you cannot draw by hand, fasten a pair of blocks on to the eye, and pull the tube out. Be careful not to damage the tube-plate. Several handy appliances are now made for extracting ferrules.

38. *Grinding in Cocks.*—In case of leakage of the various cocks, a boiler attendant should be capable of setting them right by re-grinding, unless they are very much worn, when they should be renewed. If the plugs are worn irregularly, draw-file them first of all with a smooth file as true as may be, then take either flour of emery or powdered glass, and mix with oil, and grind in the plug till it is a true fit, but not too tight, or it will be more apt to stick when expanded by the heat. Do not use a file unless absolutely necessary, and grease the cocks well when replaced.

39. *Firing Steam Boilers.*—The economical working and longevity of a steam boiler depends, in the first place, largely on the following points:—(1) The type of boiler employed; (2) how it is fixed; (3) the fuel and feed-water used. In selecting a boiler, the chief points to bear in mind are what kind of water and fuel it will be necessary to use. The feed-water should in all cases be tested, and, if found impure, of course a simple form of boiler, easily cleaned, should be selected. In any case, for economical firing—whatever type of boiler is selected—the author recommends the employment of a fire-box or combustion chamber of ample dimensions. There is little doubt that hundreds of boilers are in use in which the combustion chambers are far too cramped; consequently, to keep up a fair head of steam, excessive firing has to be resorted to, the result being the reverse of economical, both as regards the consumption of fuel and the longevity of the boiler.

Having selected the best type of boiler for the special purpose to which it has to be put, the very important question presents itself, which is the best way of firing it—or, in other words, the best way to consume the fuel employed—so as to ensure perfect combustion, at the same time securing the largest possible amount of duty from each ton of fuel employed? The effective combustion of fuel may be said to depend chiefly on the following points:—

(1) Construction of the combustion chamber or fire-box. (2) The admission of the right quantity of air to the furnace. (3) The proper regulation of the draught. (4) Regular and even firing. (1) Many Cornish and Lancashire boilers have been built in which the combustion chamber has been made much too shallow and of too small cubic capacity, with intention, probably, of bringing the fire as near the boiler as possible, and thus extracting more heat from it. This idea must be held to be altogether wrong, as in the confined space the draught is much increased, and the heat, therefore, is carried rapidly away. The small size of the furnace also will not alllow of the perfect combustion of the various gases; and, lastly, the fire itself comes in direct contact with the boiler-plates, which should be avoided. (2) The admission of the right quantity of air to the furnace is a matter of great importance, but one often neglected. In the first place, care must be taken that sufficient air space between the fire-bars is allowed. It is impossible, however, to lay down an absolute rule as to what is the proper amount of air space to secure the most perfect combustion, as much depends on the nature of the fuel and the velocity of the draught through the flues; but, roughly speaking, an area of from five to six square inches for each square foot of grate surface should be provided. The air admitted through the fire-bars is not, as a rule, sufficient to promote efficient combustion, and air is usually admitted through the door or bridge of the furnace. The author is of opinion that hot air admitted from the bridge is efficacious in promoting combustion and preventing smoke, and several very excellent plans for supplying and regulating the hot air are in use. Forcing a boiler has a tendency to produce smoke; the great factor in perfect combustion I take to be plenty of grate area and combustion space. It must be borne in mind that when fuel in a furnace is in a state of combustion, it burns of the carbon it contains only an amount proportionate to the amount of oxygen that is brought in contact with it. In order to enable that combustion to take place, the oxygen must be raised to a high temperature before it will combine with the fluid carbon. If it does not combine with the fluid carbon, it drives the latter before it until it reaches the outside air, and disperses in the form of carbonic oxide or carbonic acid gas, as the case may be. Where the atmospheric air (or oxygen) is admitted through the door and front bars of the grate, the velocity of the draught is usually such as to drive the atmospheric air straight over the bed of the furnace, and, before it has reached a degree of heat high enough to enable it to combine with the fluid carbon evolved from the coal, it is driven over the fire, and, consequently, instead of combining with the fluid carbon, it drives it to the upper air unconsumed. Various systems of mechanical stoking have been introduced during late

years, in some cases with considerable success; but exigencies of space prevent more than a passing notice here. Whatever kind of stoking is pursued, it may be taken as an axiom that the shallower the combustion chamber is, the lighter should be the fire in proportion.

## THE SAFETY BICYCLE: ITS PRACTICAL CONSTRUCTION, ETC.

BY A. S. P.

BRAZING FRAME—BRAZING WITH FIRE—BRAZING WITH BLOW-PIPE—BRAZING WITH FIRE AND PIPE—BRAZING: HOW DONE—SIMPLE BRAZINGS—SOCKET JOINTS—PRECAUTIONS IN BRAZING—BRAZING LUG OF HANDLE-BAR—BRAKE WORK.

WE have now arrived at the brazing of our frame. By brazing is meant hard soldering—or brass soldering, as it is called. Brass solder is not merely brass filings, as many imagine, although soft brass filings may be used for that purpose. Brazing metal is specially prepared for brazing, and the proportions, as given in "Spon," are: copper 2 parts, zinc 1 part. Brazing may be done with a fire only, with a blow-pipe only, or with both in combination. For my own part, I use a charcoal fire only, raising the wind with a small fan worked by a lever. The forge, with its wheel gear and 7 in. fan, cost me £3 5s. Charcoal is preferable as a fuel, as it gives greater heat than coal, and has little or no smoke.

The mischief of brazing with a fire only is that the under side of the part being brazed gets more heat than the upper, whereas the heat should be equal all round. The mischief, therefore, to guard against is the burning of the tubes on the under side before the upperside is sufficiently heated to make the brazing metal or spelter run. If a tube, which is at best but $\frac{1}{16}$ in. thick, gets partially burned, or even blistered, it is practically ruined for its purpose, and had better be thrown aside. To braze without a fire requires a good strong blow-pipe, with a gas supply of not less than $\frac{5}{8}$ in. pipe, inside measure. The blow-pipe, as most folks are aware, is fed with gas (common house gas) and air in combination, the air serving to intensify the gas flame; the air blast is produced by a bellows, and the blast must be sufficiently strong to make the most of the gas combined with it in producing heat.

To braze with a blow-pipe only, a carbon brick or a lump of good charcoal is placed beneath the joint to be brazed. The blow-pipe, if efficient, will heat up the metal to a proper degree in a few minutes, also the charcoal block, thus practically heating the metal all round. This is the cleanest and safest method of brazing, as the upper side is, if anything, heated in a higher degree than the under, and if it is removed as soon as the spelter runs there is no danger of burning; the heat also has been concentrated on the desired spot, and a much less length of the article has been heated than with the open fire.

To braze with the fire and the pipe in combination is the speediest, but great care must be taken that the fire does not heat the under side to burning before the pipe which is operating on the upper side has made the solder run. Brazing by this requires, of course, the fan forge, and also a separate bellows for the blow-pipe, which means a lot of money, and need not be adopted if the blow-pipe alone is of sufficient capacity. Thomas Fletcher, of Warrington, supplies a blow-pipe and foot bellows suitable for bicycle work, the price for the two being about 50s. He also sells the carbon bricks. Now, as I use only the charcoal forge for brazing, I will describe the process usually followed.

Suppose you are ready to begin brazing, you provide yourself with spelter and borax, the borax, which is bought in a powdered state, being used to aet as a flux to make the spelter penetrate the joint. We will take the simplest joints first.

Fig. 24.

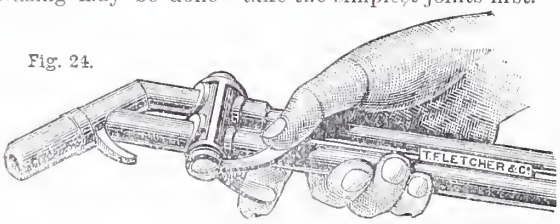


Fig. 25.

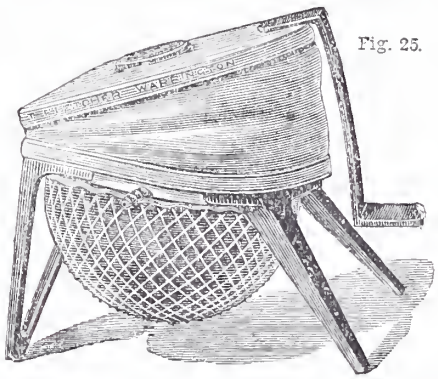

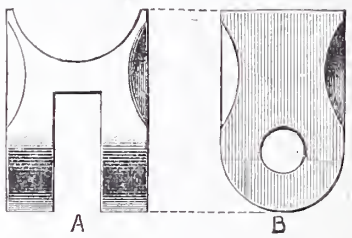

Fig. 26.

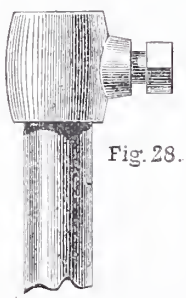

Fig. 28.

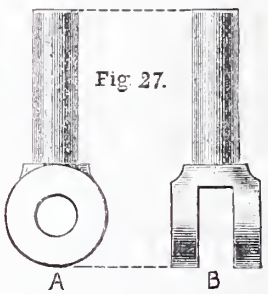

Fig. 27.

Fig. 24.—Fletcher's Blowpipe. Fig. 25.—Fletcher's Bellows. Fig. 26.—Brake Lever Lug: full size.
Fig. 27.—Fork Ends for Brake: full size. Fig. 28.—Collar for Brake Tube: full size.

We will go back to Fig. 1, which accompanies the first paper of this series (page 33) and where the parts are all lettered, or if you have a working drawing prepared and lettered, as directed in a former paper, you will find the tubes E and F converge at the rear forked stamping. Here we have two joints which are about the easiest to braze in the whole frame. There are a pair of these V-shaped parts of the frame, and, assuming that they are properly fitted, both set at the same angle, and pinned ready for brazing, fill all screwed holes with moistened clay—pipe-clay will do; tie a bit of No. 16 soft brass wire round both tubes just over the joints, moisten a little of the powdered borax in a dish with water to the consistency of thick cream, drop a little of this into each tube, along with as much spelter as a threepenny-bit would lift, and let them settle on the solid tenons inside the tubes. Having made a small clear fire of charcoal, place the work over it, heat up the parts a little, and put some of the moistened borax just over the brass wire at the joints; the steel should be hot enough to make the borax fizzle, and it, in conjunction with the borax inside the tube, will run in all over the parts to be brazed. Now provide a bit of pine wood to burn over the joint; this is the substitute for a blow-pipe: its purpose is to help heating the upper side of the work, which it does surprisingly well if properly managed. Now place the work over the centre of the fire, and blow, not too strongly; apply a little dry borax over the wire, and take care to hold the work so that the solder inside the tube does not run out. Now, while blowing, place the bit of wood over the joint, when it will burn fiercely, and throw its flame downwards on the work. When the under side gets nearly up to white heat, turn the work over, and apply more borax to the upturned side, and keep the wood still burning. In a few minutes the wire will run and disappear, and a yellow flame will indicate that the spelter inside has also dissolved. The instant the wire disappears lift the work from the fire, and hold it so that the spelter inside will settle in the bottom, which is the solid tenon. Throw a little common salt over the heated part, then scrape off all scale with a bit of iron, which will leave the work much easier to file up afterwards. To cool the work, it should stand till the red heat disappears; then it should be dipped in and out of water several times, or water allowed to trickle on to it till nearly cold. If it were left to cool without water, the thin tube would be cold long before the solid part at the joint, and the tube would be found to be hard and brittle; so in cooling with water the object is to cool down the solid parts as quickly as the tube. The two joints on this part of the frame would both be brazed at onee, as, being so near each other, there is no difficulty in heating up both at once; the thing to watch is to have both up to the same degree of heat, so that the wires on both will go simultaneously. Another simple brazing joint is the T-piece to the handle bar. This, of course, must previously be set to the angle shown in Fig. 1, formed by K, the extension tube, and L, the handle bar. Here there are also two joints, but they are so close together that they are brazed as one. The extension tube, K, must be pinned to the T-piece, and that piece to the handle bar; bits of wire are tied round as before, and spelter and borax applied in the same way. Care should be taken to tilt the job in such a way on the fire that the wire on the handle bar will run into the joint. This part will heat up and braze very quickly, there being hardly any solid metal. A rather more difficult brazing is the triple joint at the front fork crown. The two fork ends (Fig. 20, page 308) should first be brazed into the lower fork ends before pinning on to the crown piece. These ends, after being brazed, should also be filed up and bored for the axle, after which they may be pinned to the crown piece, as also the steering tube, G (Fig. 1). These three joints will be heated

id brazed all at once, with the forks lying
the fire edges up, and the steering tube
mewhat elevated, so that the solder inside
may lie at the bottom, where it is wanted.
he two forks, which are now closed at their
wer ends, should have each a small ventilat-
g hole bored, and before pinning on, each
rk should have some moist borax and
elter placed inside; the vent holes are
allow the steam to escape. Tie bits of
ire round all three joints as before, and
ve a bit of wood at least 3 in. broad to
rn over. Turn the job upside down, as
fore, to prevent burning, which would be
re to happen before the upper side was
t enough to dissolve the wires. The
ject of turning over is to get the cold side
ated up, as the other, the upturned hot
de being kept so by the aid of the burning
ood. With a blow-pipe all these joints
ould be done separately, one after the
her, and no wood used. I would strongly
lvise any one attempting the brazing of a
ece of work such as this, if he can at all
ford it, to provide himself with a good
low-pipe and foot blower. There is then
risk of burning, the work is much cleaner,
d much easier filed up afterwards. In
e illustrations accompanying this chapter,
ig. 24 is Fletcher's No. 8 C blow-pipe,
rice 10s. 6d. This pipe, with a sufficient
pply of gas and air, is ample for all the
azing of a bicycle frame.

Fig. 25 is Fletcher's 9 C foot blower, No. 5,
r supplying air to the above blow-pipe.
is priced in his list at 35s.

We have two small simple brazings in our
ame before we tackle the socket joints—
mely, the two small cross-pieces on the
rward ends of the lower rear tubes, E.
hese pieces are not at right angles with the
bes, but slope a little backwards, as will
e seen by reference to Fig. 1, and in detail,
ig. 5 (page 168). These two pieces should
e brazed into their tubes before the latter
re brazed into the rear fork stamping. Now,
to the socket joints. We have six of these
-two at the steering barrel, two at the bot-
m braeket, one at the top of tube D (Fig. 1),
d one on the front of seat pillar socket.
our of these joints are $1\frac{1}{8}$ in. tube, let into
e sockets, and two are $\frac{7}{8}$ in., also in sockets.
he inside of all the sockets should be bored
ut clean, and the tubes outside, for an inch
f their length, cleaned by filing; also when
he tubes are all fitted in their places, that
art of the frame, when laid over the full-
ize working drawing, should coincide ex-
ctly. Before pinning these joints, care
ust be taken that the frame is out of twist
-that is, the barrel part and the bent tube,
part must be in line or in the same plane.
When setting the frame, it is as well to have
he front steering tube with fork in its place
n the barrel. The frame may now be
xamined as to twist, and the joints may be
inned by inserting a screw through one
ide of each. In brazing these joints no
pelter is put inside the tubes; a bit of brass
vire is tied round each on the tube, close up
o the socket end, and the same operation is
one through in brazing as before. These
oints will heat up quickly, as there are no
olids inside the tubes. When the borax
laced over the wired joints melts and looks
icky, a little spelter may be added over the
vire, in case the wire should be insufficient.
There is no need to turn over the work in
razing these socket joints, as the burning
vood over them is sufficient to heat up from
he first.

A precaution in brazing is to protect all
inished parts as much as possible from the
ire, all screw holes or sockets being filled with clay. The steering barrel should be filled, at least at the ends, with it, as also L-pin socket and the two ears (Fig. 9, page 168) that receive the rear tubes, F.

We have still one or two small brazings; one of these is a lug (Fig. 26, A B), which is brazed to the underside of the handle bar, some four inches to the right of the T-piece. The hollow end is neatly fitted to the bar, then fixed with a screw, and brazed. Its purpose is to hinge the brake lever, it acting as a fulcrum.

Coming to the brake work we have a tube, M, some 9 in. long, and $\frac{3}{8}$ in. diameter; this has a brazing at both ends. On the lower end is a small fork (Fig. 27, A B). The shank of this is let into the tube, the tube being filed on the end to fit close. The upper end of the tube has a small split collar, or a collar with a snug on the back, as Fig. 28, for a set screw. It is used for the adjustment of the brake rod along with the handle bar, which will be noticed when we come to fit our brake work. Our frame being now brazed up, the filing up has to be gone into. All parts that have seen the fire will give most labour in filing. The rough scale should be removed from these parts with a used file, then better files may be employed; all parts that have seen borax must be filed up clean, as borax left on will soon show itself on the finished machine, even through the enamelling. If the tubes have a good clean surface they need not be filed in their length; a good rubbing with emery and oil will be sufficient, but for a nice job, when enamelled, all parts filed should be as smooth as the body of the tubes, for enamel is not intended to cover up rough work. I never use any other than files and emery to finish up frames for the enamel; for the parts to be polished for plating I use emery wheels of various grades. The emery wheels are wooden discs covered with leather, and coated with emery. Three or four of these wheels are sufficient; and for the final finish a wheel with pumice-stone or Tripoli powder, if a very fine finish is wanted. The emery wheels have each a spindle of their own, and they are mounted one at a time in a frame similar to a knife-grinder's, driven by two treadles. I use also an 8 in. grindstone in this frame, which is very useful for taking down rough parts, as well as for grinding small tools, twist-drills, &c. Having filed up our frame, which as yet is in three parts—the part in front of the driving wheel and the two V-shaped parts which constitute the rear portion. To fit these portions together we fit the upper ends of the tubes F into the lugs prepared for them. If the tubes have been cut the proper length and set aright, the forward ends of the lower tubes, E, should abut neatly against the edges of the bottom bracket, when they may be marked for boring the $\frac{5}{16}$ in. bolt holes. When these are bolted secure in their places and the upper ends of the tubes F fixed by a small flush set screw each, our frame may be considered finished and ready for the various attachments, such as brake, mud-guards, L-pin, &c., which I will treat of in my next paper.

In the meantime, if the reader has already started on making a bicycle for his own use, he may profitably occupy his time in studying what I have said about brazing, and in endeavouring to make himself a proficient in the art. Nothing can be effectually done in manual work of any kind without practice, and this is the reason why many a well-intentioned amateur fails in competition with the professional. He cannot have sufficient practice.

## SOME SUGGESTIVE SCRAPS OF STONE CARVING.

BY ARTHUR YORKE.

THE accompanying illustrations of architectural enrichment were sketched by the writer in the Chapel of the Velez family, Murcia Cathedral, Spain, and to carvers both in wood and stone they will probably suggest some departures from the beaten track.

In plan, the Chapel of the Velez differs in no respect from many chapels attached to foreign cathedrals, nor does it in the leading lines of its architecture; but in the ornamental details of its carved stone-work a style has been carried throughout which

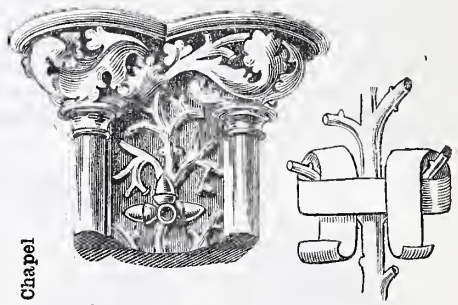

Fig. 2.—Ribbon on Leafless Twig.

Fig. 3.—Ribbon on Leafless Twig.

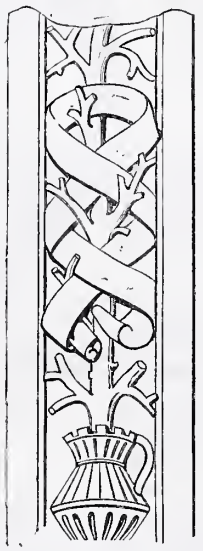

Fig. 1.—Capital and Shaft of Column in the Velez Chapel Murcia Cathedral.

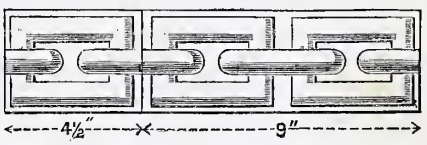
Fig. 4.—Example of Chain Moulding.



stamps it as the work of no mere copyist. In architectural decoration generally, foliage, either natural or conventional, has been depended upon for the purposes of enrichment, but in this instance the designer has almost entirely discarded leaf-work, and boldly relied upon stems and branches for his effect, foliage being reserved either for string-courses or else for capitals, as in the example (Fig. 1). To avoid monotony, and give the eye that pleasure which results from variety of form, he has hung here and there upon the bare twigs which shoot from the stems, ribbons arranged in various ways, examples of which may be seen in the lower part of Fig. 1 and in Figs. 2 and 3. He does, indeed, occasionally use a leaf, but it appears much like an exception put in to prove a rule. Even corbels are in many cases formed entirely of branch-work, the

interlaced twigs being generally cut out clear of one another, except where contact was required for the sake of strength.

The style of the Velez Chapel is Transitional, of the time when late Gothic was merging into the Renaissance, as may be seen by the shape of the vases and the treatment of some nude figures introduced here and there. Grotesques occur in places, but these are by no means "strikingly expressed in fancy," as are those of about the same date found in our own country. On the outside of the chapel, however, is a string-course of very unusual design: it takes the form of a gigantic stone chain extending all round the building. The visitor is told that a chain was the badge of the house of Velez, and hence its introduction. Be that as it may, it might suggest an unhackneyed enrichment in stone carving apart from any such motive; or with still better effect, perhaps, it might be produced in moulded brick-work. Fig. 4 shows the pattern divided for this latter purpose into a "header" and a "stretcher."

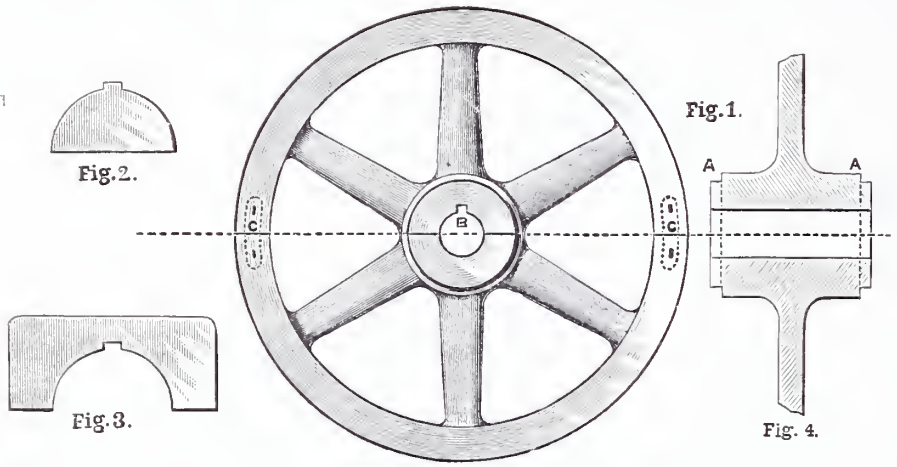


Fig. 1.—View of Wheel showing Keyway at B, and Dowels and Tapered Keys at C, C. Fig. 2.—Gauge to be fitted to Wheel. Fig. 3.—Gauge by which Key is to be fitted. Fig. 4.—Section of Boss, showing Recesses for Hoops at A, A.

## SYSTEM OF FITTING FLY-WHEEL TO SHAFT.

BY T. R. BLACKETT.

KEYING BY SUNKEN KEY IN SHAFT—TURNING AND BORING WHEEL FOR SHAFT—CUTTING KEY-WAY—GAUGES—TWIST IN KEY—PLANING-DOWN KEY—SAVING OF TIME AND LABOUR BY PROPOSED METHOD.

AT the present time, when severe competition is the order of the day, it behoves workmen to acquire methods by which they can turn out their work with dispatch and accuracy to compete with the market.

The fitting of a heavy fly-wheel (say one of about 6 tons weight) is a job that has to be carefully done, so as to ensure an accuracy that we can depend upon.

Many engineers design fly-wheels with the arms keyed to the boss, the arms in their turn to be keyed to the rim of the wheel.

Let us consider as an example that we have to key a fly-wheel of 12 ft. diameter and about 6 tons in weight, cast in two pieces, and to be fitted to a shaft 14 in. diameter by a sunken key bedded into the shaft (Fig. 1).

After the faces of the wheel that go together have been turned up or planed, the rim is secured together by dowels and tapered keys, after which it can go to the lathe to be turned.

It will be as well to remark here that after the four tapered keys have been properly fitted, temporary keys are to be substituted while the wheel is being turned.

In the hands of the turner the wheel is turned and bored out to fit the shaft, as well as two recesses (A, A, Fig. 4) turned down at each side of the boss to take two wrought-iron hoops, which are shrunk on when the wheel is permanently fixed in position on the shaft.

Having been turned, the wheel is now taken apart, and the key-way slotted out (B, Fig. 1) in the strongest part of the boss of the one half wheel.

Assuming that the key-way has already been cut in the shaft, and the key made an accurate fit, but not caulked in, we now proceed to fit the wheel to the shaft.

Many of our mechanical readers are perfectly aware that while a key-way is being cut or slotted out in a wheel, there is a certain amount of spring on the tool, which will be rather considerable in the case of a boss some 14 in. or 15 in. in thickness. This has now to be removed.

We proceed to make a gauge similar to Fig. 2, and fix it to the deepest part of the key-way, which will be the side that was lying upwards on the slotting machine. With the assistance of a crane, we lay the fly-wheel in its rim with the boss upwards, and with a file file out the key-way so that the gauge will be an accurate fit from one end to the other.

Having satisfied ourselves that this is done, and that the corners are also nicely squared out, we go about making a second gauge, which is, so to speak, the negative of the other (Fig. 3). I may here remark that before cutting the key-space in this gauge, the gauge itself should be made a good fit to the shaft, or, better still, rough out the key-space, and finish it after the gauge has been fitted to the shaft.

We now take the first gauge that we have made, and make the second one (Fig. 3) an accurate fit to it. Having done this, we try our new gauge on to the key and shaft in the position the wheel will have to go, and perhaps we find that some $\frac{1}{8}$ in. or so has to come off the top of the key.

By this method we will see if the key has any *twist* or not, and whether it will fit the wheel. Supposing, however, that we have only $\frac{1}{8}$ in. to come off the top of the key, we fit the key to the gauge: that is, we cut the key down at each end for the space of $\frac{1}{2}$ in. along until the gauge is a perfect fit to both shaft and key.

We now take the key to the planing machine and get it planed down level from one end to the other, but not to go below the spaces at each end. Having gone through this process, we place it finally in its seat or bed and caulk it up: that is, caulk the edges of the key-way in the shaft all round the key.

Having tried the gauge on, and making sure that it fits accurately all the way along, we take off the sharp arris and try on a half-wheel, which, if the foregoing instructions have been properly carried out, will be an accurate fit.

What I have endeavoured to point out in this paper is the great advantage of a good method or system. Making a pair of gauges for a job like this out of $\frac{1}{16}$ in. sheet iron would take very little time and trouble, and in the end would prove a great deal handier than using callipers. If we had had to try the half wheel (some 3 tons) off and on while we were cutting down the key, we would have taken at least three times the time, as well as incurred an unnecessary waste of labour.

## OVAL AND CYLINDRICAL VESSELS IN SHEET-METAL WORK.

BY R. ALEXANDER.

CYLINDRICAL VESSELS—WIRE BAIL FORMER—FISH KETTLE AND OVAL BOILERS—SIZING OF ARTICLES—TURNING AND SHAPING—DRAWING PATTERNS—COVERS—CUTTING OUT COVERS—OTHER STRAIGHT-SIDED WORK: WATER POTS, BOILER FILTERS, AND TOILET CANS—WIRING WATER-POTS, ETC.—HANDLES.

*Cylindrical Vessels.*—The method of making a saucepan described in Vol. II., pages 468 and 661, will serve as a guide to the making up of other articles of a cylindrical form such as camp kettles (Fig. 1). These are exactly the same in shape and size as sauce pans; the difference is that, instead of a handle, boss, etc., they have two ears and a wire handle or bail. The mode of putting on ears has already been described: the bail should be of a length sufficient to drop one-third of the depth of the body when hooked in the ears; the ends of the bail should be annealed if they are of hard wire and then bent round on the tip of the extinguisher.

*Wire Bail Former.*—A useful tool for bending wire bails quickly and truly is the wire bail former (Fig. 2). Care should be taken in fitting on the ears to keep them well out from the body, or when the bail is in it will be a difficult matter to get the cover on and off. The rims of the covers should be tacked a shade looser than the saucepans, as there is no handle to aid in taking the lid off to examine the contents whilst cooking—a loose-fitting lid is a fault that may be called a good one, but a tight lid is detestable.

*Fish Kettles, etc.*—Very similar in process of manufacture are fish kettles and oval boilers (Figs. 3 and 4). These are both of a similar shape: a kind of flattened ellipse or oblong, with rounding corners; Fig. 5 shows the correct shape, though it may be varied slightly in the case of the oval boiler by making the side a little more rounding (see dotted lines), but in the fish kettle the sides must be straight. Boilers or oval camp kettles are cut deeper than fish kettles, as a fish does not need a lot of water to cook it, and nothing else is cooked with it, whilst the boiler is often used for meat and vegetables at the same time, with, perhaps, a pudding into the bargain.

*Sizing of Articles.*—The following are

the usual sizes for oval boilers, with the way of cutting the stuff: 2 gallons, 2 single lengths and piece, 2¼ in., depth, 8½ in.; 2½ gallons, 2 single lengths and piece, 3½ in., depth, 9 in.; 3 gallons, 2 single lengths and piece, 5 in., depth, 9 in.; 3½ gallons, 2 single lengths and piece, 7 in., depth, 9½ in.; 4 gallons, 3 single lengths, depth, 9½ in.; 5 gallons, 3 middle lengths, depth, 10¾ in.; 6 gallons, 3 double lengths, depth 12 in. These measures of capacity are only to be taken as approximate. Fish kettles are not stated as holding so many gallons or quarts, but run by numbers, as Nos. 1, 2, 3, and so on; the smallest size made is 2 single lengths cut 5 in. deep, and they may be made up to any size required, as follows: 2 middle lengths, 5½ in. deep; 2 double lengths, 6¼ in. deep; two 20 in. lengths, 7 in. deep; 4 double breadths, 8½ in. deep; and so on. It will be seen that these articles are sized to cut the stuff out nearly full, thus avoiding waste and simplifying the remembering of sizes. In the making up, all the directions previously given for the saucepan apply equally to these articles as far as "wiring."

*Turning and Shaping.*—In turning and shaping, several ways may be adopted; they may be turned in the roller to a smaller circle than would be found necessary if rolling round a saucepan (see Fig. 7); the part A is then pressed against the bench to flatten it in sufficiently; this releases the part B, which is flattened in the same way; this brings the article to the same shape shown in Fig. 8; it must then be placed on a stake, and the part C rounded in a little till D and E meet, when it can be grooved together and the shaping finished, when it should be as Fig. 9; if there are two seams, they should be at the two ends A and B; if four, they must be as A, B, C, and D. It is important to get the seams of these oval articles in the proper position; that is, supposing the sides are parallel. A line drawn from the seam at one end, parallel to one side, should pass through the other seam. Fig. 10 shows seams in wrong position, but exaggerated for clearness; it will be seen by the dotted lines where the seams should be; of course, if these end seams are wrong, the side ones will also be wrong (this refers to articles in four pieces). Another method that is adopted—especially where there are no rollers—is to work the bodies into shape on the block by placing the wired part over a hole, and striking it with a block hammer, commencing at the ends and then the centre; they can also be bent on the former.

*Drawing Patterns.*—To draw the pattern of any oblong with semi-circular ends, proceed as follows (see Fig. 10 A): Draw a line, A B, of any length longer than the longest diameter of the article, and through the centre of the line, and at right angles to it, draw another line, C D, of greater length than the shortest diameter. From the point of intersection of these two lines, set off F and E, equal to half the length of the pattern. From F and E, with radius equal to half the shortest diameter, describe the arcs H and G, and with the same radius, from G and H, describe circles, or arcs of circles, I J K L and M N O P. Produce diameters R S and T U through each circle parallel to C D; two straight lines joining them and touching the circumferences of the circles at ×, ×, ×, ×, complete the figure. In all patterns cut the true pattern first and allow for fold; turn up, wire, or lap afterwards. The edging, putting on bottoms, soldering, etc., will be much the same as previously described. I might remark here that it is rather difficult to turn up the edges of the bottoms in the jenny, as the sides being straight, they have a tendency to run out of the machine. The handles can next be put on; some have swing-bail handles and ears, some end handles.

*Covers.*—The covers next call for some explanation; the articles being oval, the rim that would do for a saucepan will not do for a boiler or fish kettle, because if flattened at the sides it would rise, and so not touch the body at that part. Some get over the difficulty by making the rims perfectly straight and tacking them very slack, and throwing off a wide edge; but this is not workmanship. The way to make them is as follows: let us suppose Fig. 11 to be a plan of the top; the parts of the rim from A to A and from B to B must be cut straight, and the other parts cut from the flue rim; and in tacking the rims they would have to be tacked as follows: one straight piece would be laid on the tacking-board along the straight line, and then a curved piece tacked to it, following the curved lines; draw this over to the curve on the left side of board, take another straight piece, and lastly the other curved pieces; it would then look like Fig. 12, and when folded and turned round, would be tapering inwards all round, and when edged laying level round the wire.

*Cutting out Covers.*—In cutting out the covers for oval goods, it must be noted that an allowance must be made different from that of round covers. In allowing for a round cover, there must of necessity be the same allowance for hollowing all round extra to the size of the rim, or it would not be a round cover. But in the case of an oval it is different: it is found in practice that in hollowing up an oval or oblong the sides contract, as it were, and that if extra allowance were not made at the sides, the hollowed up cover if laid upon a flat surface would leave at the side a space of about ⅜ in. from the table or surface on which it was placed; to obviate this, so much extra must be allowed on the pattern, as shown by the dotted lines in Fig. 11; also in hollowing up, the ends must receive the most attention; the sides will want very little (comparatively speaking), and should be hollowed over a shallower place in the bench than the ends. My father used to say "Hollow up the ends well, and the sides will look after themselves." The remainder of the process for the cover will be the same as for saucepans.

*Other Straight-sided Work: Water Pots, Boiler Fillers, and Toilet Cans.*—Water pots are usually round, though there are several registered designs that are oval in shape; boiler fillers are round, and toilet cans oval (see Figs. 13, 14, and 15); and notice difference. Fig. 13, the water pot, is round, with a hollowed top, longish spout with a rose at the end, cross and back handles. Fig. 14, the boiler filler, is round, with hollowed top, cross and back handles, but with a short spout fixed higher up the body, and with a bent nozzle. The toilet can (Fig. 15) is oval in shape, cross and back handles, with hinged cover, and a spout similar in shape and position to the boiler filler. So much for their shapes. Now a few words as to construction:—Each is made in varying sizes—the toilet can and boiler filler in about three or four; water pots in perhaps a dozen. Cut as in the previous example, as full out of the stuff as possible, as follows: Water pots, half a single, 14 × 5; half a middle, 15 × 5½; half double, 17 × 6¼; half 20, 20 × 7; middle in halves (middle plate cut in two pieces, 17 × 7½), and double in halves; two singles, two middles, and two doubles, and so on. Boiler fillers and toilet cans usually only the three last sizes. The marking-out, cutting, and notching will be the same as previously described; then, supposing there were six in number being made, which would be twelve pieces of stuff, six of them must have a hole cut in them for the spout; find the centre, and draw a perpendicular line through it from top to bottom, then two-thirds from the bottom (for toilet cans and boiler fillers), and one-third from the bottom for water pots is the proper position. Punch a hole with a large hollow punch, and flatten down. Some punch a hole and a half.

*Wiring Water Pots, etc.*—This class of articles are wired differently to those just described. They are what is called "sunk-wired." Figs. 16 and 17 will show what the difference is. This necessitates the bodies being grooved together in a different way. Instead of the folds for the wiring being uppermost on the tool, it must be turned down, so that when the wire is sunk it will be on the right side—the exception to this is when the grooving of the seams is to be inside, in which case proceed in exactly the way described for examples already given. The object of sinking the wire is for convenience in soldering on the tops. The wire can be sunk as it is put in by wiring over a suitable size crease in the crease-iron, or it can be plain wired first and then sunk, either in the jenny or crease-iron; turning, seaming, edging, etc., as before described. After the bottoms and studs are put on, the next thing will be to make and put on the back handles. Fig. 18 shows the shape of the flat pattern; Fig. 19 the flat pattern of the boss for same. The boss is bent on the beck iron or in the boss former (Fig. 6), which saves a lot of time in making up a lot.

*Handles.*—Handles for water pots are wired differently to those for toilet and boiler fillers. In the two latter the wire is cut off at the ends as short as possible; but in the case of water pots it is left out at the large end an inch (each side, of course). Fig. 20 shows the handle bent round into shape, and with the wire bent in position for putting on to the can. To put them on, mark a central line between the two seams, and punch two holes with an awl—one each side of the line, and the width apart of the handle. Push the wires through, and draw them tightly over the wired edge of the pot, and nip close with the flat-nose pliers. The bottom part is then riveted and soldered, and the iron just drawn across at the top part.

Toilet cans and boiler fillers have the back handles riveted on. They are first tacked at the top along the wiring of the cans, and then two rivets are put in the top part and one in the bottom, and the bottom part soldered. All back handles are "sunk-wired," and all have bosses, which are soldered in before they are put on to the cans, and all have thumb-pieces. Figs. 21 and 22 show flat pattern of same, and bent into shape.

Particulars of spouts, top, covers, roses, etc., will be given in my next paper on the subject. Sufficient has been said here to employ the mind and hands of each who reads these articles until the next of the series appears. The illustrations to which reference has been made above will be found grouped together on the next page on a sufficiently large scale to show very clearly the mode of procedure to be followed by readers who wish to be sheet-metal workers.

# NOTTING, SPLICING, AND WORKING CORDAGE.

BY LANCELOT L. HASLOPE.

## TIES AND LASHINGS.

EDDING KNOT, OR TIE—CHAIN KNOTS—CROSS LASHING—NECKLACE TIE—PACKING KNOT—FINISHING OFF AND WHIPPING — NIPPERING, OR RACKING—WEST COUNTRY WHIPPING—SECURING BLOCK TO ROPE—CATSPAW.

IG. 68 is a "Wedding Knot" or tie, used r fastening together the eyes at the end of wo ropes. It is made by passing rope-arn or marline through the eyes backwards nd forwards until it is strong enough; it s then fastened by taking several turns ound the middle and fastening the ends vith a reef knot. This forms a sort of inge between the ropes.

Fig. 69.—"Chain Knot," for lashing to a par. A clove-hitch is first formed round he spar, and as many single hitches as equired are then made. It may be finished ff with any secure knot.

Fig. 70 shows another and better way of naking the "Chain Knot." In this case an verhand knot is formed at each turn, and onsequently it is much more secure than Fig. 69. This is used for bending yachts' sails to the gaff. As each turn forms a knot if the cord parts, the remainder holds firm, and does not necessarily come adrift, as it would be almost sure to do if fastened as in Fig. 69.

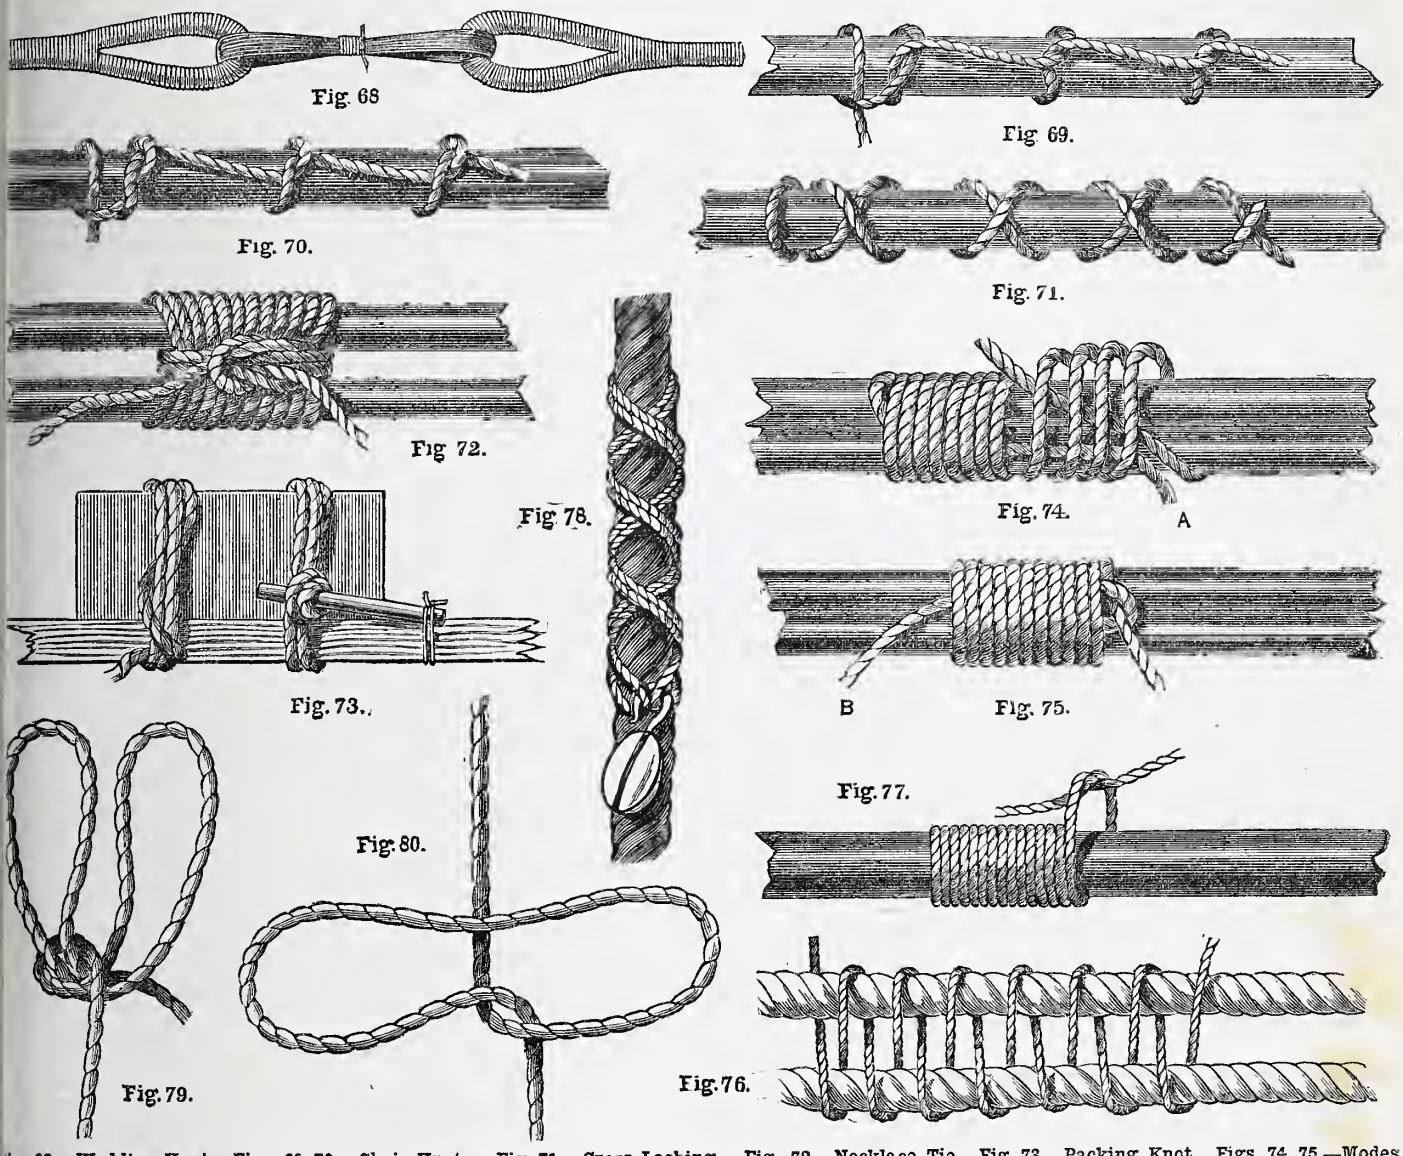
Fig. 71 is a "Cross Lashing," used when a lever is used to a rope. After several turns round the rope, the lashing is crossed round the lever and fastened with a reef knot. All these lashings are used when several men are required to haul on large ropes at the same time.

Fig. 72 is the "Necklace Tie." Several turns are taken round the spar to be joined, then two turns round the lashings, and it is secured with a reef knot. When this is used as a lashiug for shearlegs, the crossing of the two legs puts a strain on the knot, and effectually secures it. For this purpose it is called a Portuguese Knot

Fig. 73 is a "Packing Knot," used for securing large pieces of timber together. It is much employed in the neighbourhood of stone quarries in holding the blocks of stone on to the carriages on which they are taken to their destination. Fig. 73 represents a block of granite secured to a trolley with packing knots. Two or three turns are made somewhat loosely with cordage round the block and its carriage; a stout piece of wood is then inserted under the coils, and twisted round until all the slack is taken out and the cordage is taut. The end of the lever is then secured with twine to the side of the carriage, as shown in the right side of the figure. The other lashing is supposed to be already for tautening up. We have often to lash two things together where an external knot to finish off with would be objectionable, as it would spoil the smoothness and neatness of the work—as, for instance, in whipping the two parts of a broken fishing-rod together.

Fig. 74 shows one very common method of finishing off whipping without showing any knot. In commencing, we lay one end forward, as shown at A, then pass the other end round and round a sufficient number of times—hauling taut as we go; three or four loose turns are now made, and the end passed under them backwards; these are worked down into their places, and when the ends are hauled taut and cut off the job is completed. The end A need not come so far as shown in the figure, but may be hidden under the coils.

Fig. 75 is another method of accomplishing



**ig. 68.—Wedding Knot. Figs. 69, 70.—Chain Knots. Fig. 71.—Cross Lashing. Fig. 72.—Necklace Tie. Fig. 73.—Packing Knot. Figs. 74, 75.—Modes of Finishing and Whipping. Fig. 76.—Nippering. Fig. 77.—West Country Whipping. Fig. 78.—Securing a Block to a Rope. Fig. 79.—Catspaw. Fig. 80.—Ditto, Commencement.**

the same end. Instead of a single end, as in the last case, a bight of the seizing stuff is laid along the part to be whipped, and the turns passed over it; when these are completed the end is passed through the bight, as at A. The end B is now hauled upon, which has the effect of bringing the bight and the end of the rope snug under the coils. We have now two loops interlacing at the centre of the work, and which cannot come undone. When the ends A and B are cut off close to the turns, the whole is as fair and smooth as one can wish. This is the method I generally adopt myself in making fishing gear.

"Nippering," or "Racking," is shown in Fig. 76. This is a method of securing two ropes together with cross turns; these are hauled taut, jambing the ropes together, and they are further secured by round turns over all, with a reef knot at the ends.

Fig. 77.—"West Country Whipping." Whether it was invented in the West or not I do not know, but I certainly never heard of it until I came to reside in the "west countrie." It is an excellent method, and deserves to be oftener practised than it is. Bring the middle of the material used under the part to be whipped, raise the ends up and tie an overhand knot, lower the ends and tie another underneath; continue tieing a single knot above and below alternately, finishing with a reef knot—or a round turn or two may be taken and the ends secured, as in Fig. 65; but a reef knot is the most usual way of fastening off this whipping. This is not quite so neat-looking a method as Figs. 74 and 75, but it is very strong and trustworthy, and is an excellent way of fastening large hooks, such as those used for cod or conger, on to a line.

Fig. 78 shows the way a block is often secured to a rope with a selvage strop. The middle of the selvage is placed against the rope, and cross turns taken until the bights come together, when the loop of the block is put through them.

A "Catspaw" (Fig. 79) is used for attaching a rope to the hook of a tackle. Fig. 80 gives the manner of commencing it. A loop is first made, and laid over the standing part so as to form two bights; these are rolled over two or three times from you, and the hook inserted in them. When the standing part is hauled upon, the hooks take the form shown in Fig. 69, and will not slip.

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 56.—The "Electrician" Primers.

The "Electrician" Primers are published by the "Electrician" Printing and Publishing Company, Limited, Salisbury Court, Fleet Street, E.C. They are a series of tracts, if I may be permitted to use the word in reference to them, or helpful papers on electrical subjects for the use of students and general readers, and they are comprised in two volumes, each in a paper wrapper, and sold, each, at 2s., or 2s. 2d. post free. Of the two volumes, Vol. I. deals with theory, and Vol. II. with practice; but before proceeding further, I may add that the volumes may also be had in strong cloth bindings at 2s. 6d., or 2s. 9d. post free, and single primers at 3d. each, or 3½d. post free. It is not possible for me to give a list of the primers in detail, as it would take up too much space; but lists of the subjects treated may be easily obtained on application to the Company, whose address is given above. In Vol. I. there are twenty primers devoted to a digest of such subjects as Ohm's Law, Electrolysis, Influence Machines, Thermopyles, etc., and various electrical instruments, as the Galvanometer, the Wheatstone Bridge, etc., the methods and modes of making some of which have been described in these pages. In Vol. II. there are eighteen primers relating to the management, principles, and uses of various machines, including Submarine Cables, the Telephone, Dynamos, Motors, Transformers, Lamps, Meters, etc., and the action of the electric current in deposition, welding, etc. The object of these primers, which are clearly written and all that can be desired in the form of enunciation and explanation, are, to quote from the preface to each volume, "to briefly describe in simple and correct language, the present state of electrical knowledge. Each primer is short and complete in itself, and is devoted to the elucidation of some special point or the description of some special application. Theoretical discussion is, as far as possible, avoided, the principal facts being stated and made clear by reference to the uses to which they have been put. Both volumes are suited to readers having little previous acquaintance with the subject. The matter is brought up to date, and the illustrations refer to instruments and machinery in actual use at the present time."

### 57.—The Silico and Club Black Enamels.

Some useful specialities, possessed of more than ordinary value to the amateur, have been recently produced and sent into the market by the Silico Enamel Company, 97, Hampstead Road, London, N.W., the most important, perhaps, being the Silico Enamel itself, from which the Company takes its name. This is a thin, liquid enamel, which is easily applied to any polished surface and bright metals of all kinds, and when applied in the proper manner, according to the instructions given and under the conditions named, forms a smooth and transparent film on the surface of the metal which not only protects it from rust or tarnish, but makes its original brilliant appearance to be preserved and maintained unchanged under any circumstances. All cyclists possessing good machines, of which parts are nickel-plated, know how difficult it is to preserve the lustre which these parts present to view when the machine is first sent out from the works or the depôt for sale, and they will accordingly welcome this preparation, which will save them an infinity of labour in rubbing up the bright parts and keeping them in a presentable condition. Further, it is useful for all metal articles or ornaments—be they what they may—that are exposed to the action of the weather. Equally good and desirable for cyclists is the Club Black Enamel, which is suitable for application to all metal surfaces requiring japaning, whose enamel has become chipped or injured in any way, and which it is needful to renovate. The Club Black Enamel is hard, bright, and durable, dries quickly—that is to say, in an hour or thereabouts—without the intervention of heat, as in the case of enamel, which requires to be stoved, and presents not only a hard but a brilliant surface. In fact, it is a "special hard drying" preparation, and this is pointed out and emphasised on the label of the jar, on which the words, in inverted commas, are printed in red. Both of these articles seem to be making their way in public favour very rapidly. Samples of either, with full directions for use and brush for application of the enamel, may be had, in bottles or stone jars at 1s., from the wholesale agents, Messrs. W. B. Fordham & Sons, Limited, York Road, London, N., and at all cycle depôts, ironmongers, stores, etc. In putting on the enamel care must be taken to move the brush in one direction only, and not backwards and forwards.

The Editor.

## SUGGESTIONS FOR WORKERS AND HINTS TO INVENTORS.

Artificial Stucco-Work.—A new idea, which will be welcomed by amateurs anxious to decorate their ceilings without calling in the aid of the builder or plasterer, has been suggested in a trade journal by Mr. L. Bridger, of Old Manor House, Walton-on-Thames. In place of real stucco, he uses ordinary wood mouldings, about 1¼ in. deep, costing about ½d. per foot, which are mitred together at the joints, and pinned in place with French nails driven into the joists. Plaster-of-Paris is then rubbed into the joints and interstices, and painted white, the whole being then whitewashed. A very rich effect is thus produced if a sufficiency of moulding be used. The *Paper Record* points out that the use of a substance resembling papier maché, which permits of being moulded so as to form circular or curved designs, was not unknown in the reign of Queen Elizabeth, being finished off much in the same way as the wooden mouldings above described.

Spontaneous Combustion on Board Vessels.—Ingenious minds have a promising field in the way of providing against spontaneous combustion on board ship. The recent serious fire at sea on board an Allan Line steamer, which was not extinguished until the vessel had been taken into dock at Liverpool, shows that, despite every reasonable care, certain cargoes, such as cotton, are dangerous. That this material—rags, wool, etc.—will spontaneously ignite under certain circumstances is well known, but in what way this can be prevented is still uncertain. Even the means now adopted to extinguish such fires are unsatisfactory. On board the steamer in question, which was well provided with steam jets in the hold, the steam was found only to check the progress of the fire. There are thus two points for consideration—how to prevent, and how to absolutely extinguish such fires in cargo. Some apparatus which would utilise carbonic acid gas under pressure would probably meet the necessities of the case as regards putting fires out; but any one who can devise a means of preventing any such necessity from arising will earn the gratitude of, and, it may be hoped, something more substantial from underwriters and ship-owners.

Fire Extinction on Board Ship.—The comparative failure of steam jets to extinguish the fire in the hold of the s.s. *City of Richmond* has drawn public attention to the necessity of devising some effective means of dealing with the spontaneous combustion of cargoes. Various propositions have been laid before shipowners—notably one by Professor Lewis, in which the release of carbonic acid gas stored in breakable vessels is the principal feature. The whole matter, however, requires the exercise of much thought and ingenuity. The heat generated by combustion is relied on by Professor Lewis to set the carbonic acid gas in action, but captains of vessels do not seem to think this sufficiently sure. A simple apparatus, worked from the deck, which would at once discharge the gas if needed seems to be wanted.

New Games, etc.—Two things are remarkable in connection with new inventions in this line—the great difficulty in getting one to "catch on" with the public, and its immense success, financially, when that desirable end has been obtained. A similar remark applies to toys, large fortunes having been made by penny articles of this class sold in the streets. Both new games and new toys are just now in demand—cheapness of production being essential.

Perpetual Electric Clocks.—A Leeds scientist states that electric clocks can be constructed without the aid of batteries—as generally defined—by simply burying the plates in the earth, which would otherwise be excited by an acid solution in an ordinary battery, these, of course, being connected to the driving mechanism in the ordinary way adopted in electric clocks. The idea is very fascinating, and many will feel inclined to experiment in the same direction. As the statement has appeared in technical journals of repute, it is probably based on fact; but we have not ourselves had an opportunity of testing the apparatus described.

## A Corner for Those who Want to Talk It.

*** *In consequence of the great pressure upon the "Shop" columns of* Work, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* Work *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—Letters from Correspondents.

**Constructive Strength in Metal Work.**—An Engineer writes:—"I have been considerably amused in reading an article in Work of May 30th, on "Constructive Strength in Metal Work," by Mr. Harland (p. 162), and it has set me wondering where he has got his information from, as much is contrary to all ordinary practice. Perhaps you or he could inform me in the column 'Shop.' In speaking about girders, he says: 'Sometimes a second though smaller flange is made at the bottom.' I have always found that wrought iron and steel (rolled) girders have equal flanges, and that cast-iron ones have the flange in tonsion two or three times the area of the one in compression; in ordinary girders the bottom flange is the largest, thus not I He also mentions that sometimes in bridges the top flange is straight and the bottom arched, while the web is pierced. If he were to look at any such, he would find that the so-called girder was merely an ornamental casting to give a finish, that there were C.I. or W.I. girders (most likely arches) to take the weight, and this was bolted to the face of the outside one, and the bottom flange was merely to stiffen the web or spandrel. Later on, he talks about a girder being more weakened by holes in the web than the flange. So far as I have ever heard and done, the calculations for girders are taken on the basis that all shearing is borne by the web, and all bending by the flanges. The webs are always far stronger than necessary, *according to calculations for shearing*, for constructive reasons; so a hole does not make any difference, excepting a very large one, or, perhaps, at the ends or under a concentrated load where the shearing force is greatest and the excess of area the least. The bending place or moment in a girder can be resolved into a tension in one flange, and a compression in the other; and usually these are calculated closely; so any hole reduces the area and puts more stress on the rest, and thus diminishes the strength of the flange. Further on he says: 'The broader the base, the lower the centre of gravity will fall.' Will Mr. Harland kindly explain how the method of support affects the centre of gravity? I have always understood it was the point in which the whole weight may be supposed to act, irrespective of the means of support. In speaking of the A support for lathes, etc., he says that alterations of length, due to ehange of temperature, are alike on both sides; are these so much as to affect *anything* besides a sum in expansion by heat for some schoolboy? I know that bridges of 40 ft. to 50 ft. span, designed by first-class engineers, have often no allowance made for it. I should like to hear what Mr. Harland has to say, as, if he is right, I shall have to alter my methods."

Span Roof Greenhouse.

**Cycloidal Curves.**—An Old Edisonian writes:—"I cannot endorse the statement of C. E. in his reply to C. C. (*New Cross*), pages 237-8 of Work, Vol. III. The speed of any point on the surface of a revolving disc is proportional to its distance from the centre, and to say that the lower part of any wheel travels more slowly than the upper when rolling in contact with a plane surface, is an error of judgment. The fact that the path of any point on the periphery of a rolling wheel takes the form of a cycloidal curve, proves nothing beyond the simple fact that, although the wheel revolves on its axle it does not do so in a circle. Now let a wheel or dise be rotated upon its axle, and at the same time moved along a plane surface, but without actually being in contact with it, and at a speed corresponding to that at which it would move if it were rolling thereon, what becomes of C. C.'s contention? Cycloidal curves would be formed from any point of its periphery in precisely the same way, but the under edge of the wheel must move at the same speed as the upper, no matter what that speed might be." [The fact of your not being able to endorse the accuracy of C. E.'s reply does not affect its soundness. Will you demonstrate, as clearly as C. E. does, the argument you adduce to controvert the conclusion he arrives at?—Ed.]

### II.—Questions Answered by Editor and Staff.

**Model Electric Lights.** — J. H. (*Wolverhampton*).—The carbon plates for the small box battery described in Work, November, 1890, should cost about 4d. or 5d. each. Try J. Steen & Co., or Mr. A. J. Hartill, 53, Worcester Street, in your own town. If you fail these, you can have them sent by post from Mr. Bottone direct, or from any other dealer in electric sundries.—G. E. B.

**Electric Coil.**—J. E. W. (*Burslem*).—A series of articles on Coils is now in the Editor's hands. The last of the series will deal with medical coils, and you will learn from it how to construct a coil with several powers. For six powers you will require five separate lengths of wire in the construction of the secondary coil, the finish and commencing end of each length being brought out to a separate stud on the base of the coil. Or you may use one length and one size of secondary wire if you bring out a loop of the wire at the end of each fifth layer; twist the wire into a cord, and fasten each bared loop to a separate stud. Then, one wire from the primary to represent the first power, and one each from the five sections of the secondary, will form the six powers. I do not know of a book dealing with electric coils generally. The articles I have written for Work will give you much information on the subject.—G. E. B.

**Span Roof Greenhouse.**—T. N. (*Dalston*).—I give sketches of front elevation, Fig. 1; side elevation, Fig. 2; general view of framework, Fig. 3, and detail of joint at angles A, A of above. This makes rather a short doorway, but that can easily be altered in the making. I should make the sills of 2½ in. by 4½ in. oak, the four corner posts of 3 in. by 3 in. yellow, and the rest of 3 in. by 2 in. yellow. Either of the sashes along the sides can be hung for the purposes of inlet ventilation. And the space over door at one end, and the gable end of the other for outlet ventilation. Do not attempt to open the sashes at the top, for this not only entails a great deal more work, but it is a constant source of annoyance, unless it is done very nicely, and by putting the tie bolt through the top rails of frame-work, as shown at B, Fig. 3, you do away with the necessity of any intermediate rafters. The sashes need only be beaded on the outside, but do not put any beads at the bottom of sashes or match-lining in the front, but simply weather the rails to allow the water to run off; the match-lining being thinner than the sashes will allow of your beading them on both sides. The top rails of top sashes are mitred together, and a piece of ridge roll bird's-mouthed over them. The space in "Shop" is wholly inadequate for a thorough description of a greenhouse, but you will find the matter exhaustively treated in Nos. 12, 14 and 15, Vol. I., under the heading of "The Tenant's Greenhouse."—E. D.

**Watch Springs.**—Clips.—(1) Try the effect of cooling between two plates of iron smeared with oil; if after this they go wavy, your only course is to set them true by careful hammering. (2) It depends on size partly, but generally they are heated in a charcoal fire, and hardened in oil and blazed off. You can get spring steel of Pfiel, St. John's Street, Clerkenwell.—J.

**Whitening Stains.** — Anxious. — When old stained plaster work or woodwork is coated with whitening-wash, the stains invariably work through, no matter if you give it a dozen coats. The why and wherefore is a lengthy matter, and no practical advantage would accrue to you to discuss it here. To remedy the trouble, remove all old whiting, and coat the stains with oil paint, or try a wash of plaster-of-Paris and water—the latter *may* answer, the former is *sure* to. Have you tried Alabastine?—F. P.

**General House Repairs.**—A. F. S. (*Hackney*).—There is a very useful waistcoat-pocket price book, published by Spon (London), which I think would suit you, but I should advise you to call and see them, or else write for catalogue.—E. D.

**Aquarium.**—A New Subscriber.—An article on the construction of an Aquarium appeared in Part 31, Vol. I. of Work. Should this be too elaborate for your purpose, you could leave out such details as you did not desire. The instruction for any part of the design will hold good.—C. M. W.

**Sewer Gas.**—E. T. (*Burntcliffe*).—It is impossible for me to give you a test for sewer gas unless I have a rough plan and a slight description of your system of drainage, as there are so many ways by which sewer gas can find its way into a house. The ways it can do so are, for instance—1. Through defective joints, either caused by bad workmanship, settlement, or general decay. 2. Through any overflow, waste pipe from sinks, baths, gutters, etc., which, although so-called trapped, are in direct communication with sewer. 3. If there is no proper interceptor trap cutting off the house drainage from the main sewer. 4. If the house drain and soil pipes are not subject to a constant current of fresh air by means of inlet and outlet ventilators. 5. If all traps that are in the least way subject to syphonage are not relieved by an air pipe, etc. etc. I could continue for some time giving examples of how it can get into the house; but how to test when and where it gets there is useless to speculate upon without being more fully informed as to the state of things at present. There are several ways of testing if a drain leaks; by putting some nauseous or strongly smelling chemical down the drain by means of the w.c., and seeing if it can be detected anywhere about the house. I have heard of a plan by which a chemical strongly resembling the smell of cats' urine is put into the drain, and it is then left to the delicate (or otherwise) sense of smell of the domestic feline to trace the point of escape. But all these means are purely theoretical, and give nothing else but dissatisfaction, and I should certainly not think of recommending them. The remarks I have made above as to the ways the gas can enter a house may appear to you too technical, but they are not so; for if you find them difficult to understand, I feel convinced that you would not be able to give me a sufficiently clear description to enable me to be of any service to you. If this is so your only way is to call in an *expert* in sanitary matters, and let him make an examination, and give you a specification of what is necessary to be done to put your premises in thorough sanitary order, for which he should not charge you more than £2 2s. If, on the other hand, you feel confident you can give me a clear description, I shall have much pleasure in telling you how to go about finding any defects there might be, and the cheapest way to remedy them when found. But I must say this, that the appliances necessary to make a thorough examination and test are, in many cases, more costly than paying an expert to examine the drains and remedying the defects afterwards. I should have liked to have given a description as to testing a drain as it would interest so many readers; but, in order to do so, I should have to lay down a purely imaginary system of drainage for example, and perhaps this description would be a very long way from meeting your case.—E. D.

**Carpentering.**—T. G. W. (*Clapham*).—I am not aware of any book suitable for an amateur that is in any way superior to the various articles in Work. Of course, magazine articles vary; some are suitable for well-advanced students, and some for young beginners. It is beyond my province to encourage T. G. W. to hope for a weekly column—if it ever be done it must be graduated better than T. G. W. suggests. I can only advise that you watch the advertisements in local papers. My classes are at the N.W. end of the town.—B. A. B.

**Draughtsman.**—G. B. (*Poplar*) wishes to know the qualifications of a draughtsman, and asks for advice as to books and classes. One qualification of a draughtsman is undoubtedly the ability to make a drawing, more or less finished and elaborate in style according to the class of work he has to deal with; another, and in most cases a much more important qualification, is that he shall understand what he has to draw. For the draughtsman is generally called upon to invent what he draws; if he be an arcbitectural draughtsman called upon to design, say, such a comparatively simple thing as a sash-window, most likely the only data given him to work from will be the height and width of the window; it is for him to decide on the sizes, shapes, and construction of the window-frames, window-sashes, architraves, thickness of glass, and all other details necessary to make the working drawing complete. If he be a mechanical draughtsman called upon to design an iron roof, probably all the requirements that will be put before him are that it shall cover so much ground, and shall be covered with corrugated iron or slates, as the case may be. It is then the draughtsman's duty to say what style of roof-principal shall be adopted, the size and material of every member—rafters, struts, tension-rods, tie-bars, purlins—with sizes and shapes of all joints and connections, as well as the sizes and strengths of the supporting columns. So that G. B. will see that draughtsmanship, or the art of drawing, is only one of the minor qualifications of what is generally known as a "draughtsman." Before commencing to make mechanical drawings (I assume from G. B.'s letter that he is a mechanical engineer), I would strongly recommend him to work through some small book of plane geometry—there are plenty published at 6d. which are suitable—and familiarise himself with the bisection of lines, drawing parallel lines, erection of right angles under various conditions, finding centres of circles, and other simple problems. A knowledge of these will save him much future trouble.

After this, let him make copies of simple mechanical drawings, so as to get accustomed to the methods of using the instruments and the uses of sections, plans, and elevations, conventional colours for different materials, etc. After a little of this work, he should make freehand sketches of some simple piece of machinery or joinery, measure it up, and figure the dimensions on his sketches, and from these dimensions try to make a proper working drawing. He will most likely find that the dimensions are not sufficient for his purpose; that although he has taken twice as many measurements as are necessary, he is still short of some that are absolutely needed to make an accurate drawing. Only practice can cure this, though the knowledge of the geometry above recommended will assist him in deciding which are the right dimensions to take. The first drawings should all be big and bold—not "finicky"—to full size or as big a scale as possible. Draw with strong lines, but, on the other hand, let the colouring be rather pale, except in such parts as are in section. Good lettering, or "printing," and general artistic finish to a drawing are very desirable, and in some drawing offices a necessity; but there are thousands of working drawings sent into the shops with the dimensions and particulars merely written on them in ordinary handwriting. I can recommend no better books than Cassell's Technical Manuals, which are advertised in WORK at the end of "Shop." "Drawing for Machinists," price 4s. 6d., is the one that will probably suit G. B. best. Crosby Lockwood & Co. also publish "Engineering Drawing," price 3s. 6d., one-third of which might be useful. If possible, try and attend a night class under some science and art teacher. —A. B.

**Life Buoy.**—W. J. C. (*Surrey*).—Write to Messrs. P. B. Cow & Co., Indiarubber manufacturers, Cheapside, London, E.C.

**Coal Vase.**—BLACK DIAMONDS.—If you purchase No. 36 of WORK, price one penny, you will find, on p. 571, particulars of how to make a cheap coal vase; also, if you refer to the Indexes of Vols. I. and II. of WORK, several other references will be found relating to coal boxes.

**Overmantel and Coal Vase.**—G. A. H. (*Islington, N.*).—Particulars of a simple, cheap coal vase were given in WORK, No. 36, p. 571. For overmantel designs procure Nos. 5 and 22 of WORK.

**Electric Lighting Replies.**—AN OLD EDISONIAN.—Thanks for your criticisms. The pages of "Shop," Section I., are open to you, or any reader, to question the accuracy of anything you light upon in WORK, and which may not seem quite clear. G. E. B. will reply to you through "Shop." In the meanwhile, reference has been made to his "copy," and in each instance complained of he wrote *Watts*, not "volts," so that it is a printer's, not an author's, error.

**Blunders in Replies.**—AN OLD EDISONIAN—The blunders noticed by you in my reply to J. C. H. (*Dublin*), on p. 172, are manifestly either slips of the pen or printer's errors. Of course it is most unfortunate that they should have got into print, but it is evident to all, except a mere tyro, that the word "volts" is a misprint for "Watts." The sentence should, therefore, read: "Your ten lamps, of 8 c.p. each lamp, will take 280 *Watts* of current to light them. Twelve lamps will take 336 *Watts* of current." No one in his right mind would think of running ten 28 volt lamps in series from a set of accumulators, as this would involve the employment of one hundred and forty cells in series at the least. In the next sentence but one of the reply, the mistake is repeated. It should read: "Multiply the *Watts* of current by the number of hours the cells are wanted; divide this by the voltage of the cells to be used, and you will then find the desired capacity of the cells to be employed." For instance, supposing we take twelve 8 c.p. lamps. These will take 3½ Watts of current per candle power; then $3\frac{1}{2} \times 12 \times 10$ will give us 336 Watts of current as being necessary to light the lamps. I think the querist wished to know the least number of cells he could use, and the longest time he could use them. Now, if he wished to use the lamps for a twelve hours' run, and the resistance of his lamp circuit is 18 ohms, the figures will be $336 \times 12 = 4{,}032$, $\frac{4{,}032}{18} = 224$ ampère hours as the required capacity of the accumulator cells. As the eleven plate E. P. S. cells have only a capacity of 220 ampère hours, I deemed it best to have the fifteen plate size, which has a capacity of 330 ampère hours. The merits of a reply in "Shop" can only be judged by comparing it with the question to be answered. These are sometimes of such a character, as to be calculated capable of puzzling a Transatlantic lawyer.—G. E. B.

**Brass Lacquer.**—J. K. W. (*Liverpool*).—A good golden-coloured lacquer for brass is described on p. 83, No. 58, Vol. II. of WORK. You will also find recipes for brass lacquers in "Shop" (see p. 28, No. 54, Vol. II. of WORK.) As a rule, it is cheaper to buy brass lacquer ready made by professional makers. A good cold lacquer for brass is sold by Messrs. J. & E. Hartley, 13, St. Paul's Square, Birmingham.—G. E. B.

**Insulating Compound.**—J. K. W. (*Liverpool*).—I cannot just now place my hand on any recipe for making an insulating compound of gutta-percha with other substances. Gutta-percha can be dissolved in bisulphide of carbon, chloroform, and ether, and the resulting pasty mass be employed as an insulating compound. Perhaps some of our readers can describe an insulating compound of gutta-percha with other substances.—G. E. B.

**Dry Battery.**—E. W. (*Euston Road*).—Dry batteries have been and are used for working portable medical coils, but I cannot say whether the dry battery described by F. A. (*Portsmouth*), on p. 174, would be suitable or not. The mixture appears as if it would work, but I cannot say anything about the constancy of such a battery. Perhaps F. A. will oblige us with his experience. If you wish to try the mixture, use it in cells made of thick sheet zinc. Canisters 6 in. in length by 3 in. in diameter are a convenient size.—G. E. B.

**Electric Bell Battery Repairs.**—C. R. (*Mayfield*).—I cannot recognise the battery from your description of it; possibly it is a dry silver chloride battery. If so, the wire coil is a silver wire, and this has been immersed in a paste of silver chloride, separated from the zinc by a canvas or cloth partition. The zinc must be cleaned and the silver chloride renewed. I have not a high opinion of these batteries, so should advise Leclanché or Gassner cells instead.—G. E. B.

**Electrotype Copy of Hound's Head.**—C. F. (*Sherborne*).—As you have modelled the head in clay, and have taken a copy of this in plaster-of-Paris, your course is quite clear. Get a copy of WORK for August 9th, 1890, and read therein the article on "Electrotype Copies of Busts." This will give you details of the process to be followed in getting an electrotype copy of the hound's head. Of course you have the plaster mould in two or more pieces. Soak them well in linseed oil, and bake them afterwards, to make the plaster insoluble in the electrotype solution. This should be done several times. The insides of the two halves of the mould must then be coated with blacklead, as directed in the article on "Blacklead and Blackleading," in WORK for October 5th, 1889. These must now be treated as directed in the article above mentioned to get an electrotype copy, and the two halves of this copy soldered together. If you meet with any difficulty, please let me know and I will advise you in "Shop." We do not send replies by post.—G. E. B.

**Fungus.**—E. G. P. (*London*).—The only remedy for the above is the removal of the cause. The causes are generally want of ventilation. Confined air without moisture considerably assists the fungus. Too much moisture will prevent its growth, but if dampness is combined with warmth, and without ventilation, it assists its growth; in fact, all kinds of stoves increase its growth if the parts are in any way damp. Linoleum or oil-cloth is frequently the cause of dry rot, by preventing access of air and retaining the damp. The best way to treat it is to cut out all the diseased timber, and substitute thoroughly seasoned material in place of same; ventilate the cellar, and lastly, but not least, thoroughly brush away all signs of the fungus; for one of its peculiarities is that the germs of the fungi are carried in all directions in a building where it shows itself, without necessity for actual contact between the affected and sound wood.—E. D.

**Gas Meter Index.**—C. C. (*Oxford*).—You will find this question fully answered on page 541, No. 34, Vol. I. of WORK, with the correction that where it says, in brackets, "bear in mind it would have to go right round to be 1·090," "read bear in mind it would have to go right round to be 1·000."—E. D.

**Iron Roof.**—PLUCK.—There is no doubt that galvanised corrugated iron, of at least No. 20 Birmingham wire guage and properly galvanised, is far preferable to black iron sheets for your purpose, and one great consideration in its favour is, that being corrugated this enormously increases the stiffness and strength of the sheets, consequently there are less intermediate supports required. This, I think, does away with the necessity of answering your other questions.—E. D.

**Cement.**—GLASIUS.—I think you will be able to succeed with plaster-of-Paris. If it sets too quickly, mix sugar with it; alum water used to mix it with makes it set very hard, or you might use Parian cement, which would not set so quickly. I am trying some experiments, and will let you know the result if you do not succeed, and will write again.—W. E. D., JR.

**Glass Silvering.**—ANXIOUS B.—You cannot have a cheaper method than that by nitrate of silver; and as you say you have read those described in WORK, you will, of course, have seen there are many things that would account for those in the trade being able to make and sell at a cheaper rate than an amateur can produce. To mention one obvious one, all their materials are bought in quantities, and, therefore, very likely at less than half price; and it is quite right that it should be so. They have to live by their trade. A true amateur does things for the love of making and the knowledge gained, and not to compete with the trade, nor to make a profit on his work; in fact, in that case, he ceases to be an amateur. If, therefore, you want to make one or two cheaper than you could buy them, you will find it cannot be done; but if, as I said, you wish to do it for the love of it, and the knowledge gained, try the recipes given in WORK.—W. E. D., JR.

**Bicycle Enamel.**—W. L. (*No Address.*)—Get enamel paint, any colour, from an oilman. State what it is for. The enamelled plates used in advertising soaps, etc., are baked in an oven; the process is patented. Stoving enamel for bicycles would stand under water, but you would not get it white. You cannot melt the edges of glass so as to make watertight joints. Join the edges with cement used for glass work; cement of Pompeii will do.—A. S. P.

**Stains out of Books.**—BOOKWORM.—You ask how to take a water stain out of a book. I am very sorry that I cannot tell you how to do this; a stain halfway up every page is a serious affair. I am afraid your book is hopelessly spoiled. There are a few things you might try, but you would have to take the book to pieces and treat every leaf separately, and, of course, such a procedure entails no small degree of labour, besides the chance of making matters worse through the want of experience in your manipulation. A very weak solution of oxalic acid might be used as a bath, every leaf placed in separately, and allowed to remain for some time, and afterwards placed between sheets of blotting to dry. I would really advise this BOOKWORM not to attempt this. I am sure he will only make matters worse.—G. C.

**Engine Valves.**—PASSIL.—In No. 110, Vol. III. of WORK, and page 89, you will find a diagram and drawings of a plain slide-valve and its action. The description of the practical method of setting the same would take up too much space of "Shop"; it would also be impossible to mention a book treating of all the different forms of valves as desired, and, as the methods of working the same are as numerous as the valves themselves, it would want an encyclopædia on the subject to afford the information desired, and as the method of setting them would vary for each alteration in gearing, you will see that it would be an impossibility for one book to contain all the information desired. I herewith give a list of a few books relating to engine valves:—(1) "A Treatise on Valve Gear," by Zeuner; published by E. and F. N. Spon. This book deals solely with the theory, and is considered a standard work on the subject of which it treats. (2) "Sink Motion and Expansion Gear," by N. P. Burgh, published likewise by E. and F. N. Spon. This gives a pretty complete account of several kinds of valves, including Corliss motion. (3) "Valve Gears," by Spangler, published by John Wiley & Sons, 53, East Tenth Street, New York. (4) "The Steam Engine," by D. K. Clark, published by Blackie & Son, Limited. This is a costly work, as it contains four volumes; there is some useful information on valves in it. (5) "Steuerungen der Dampfmaschinen," by Emil Blaba, published by Julius Springer, Berlin. I give this as, should you be able to read German, it seems more of the style of book you want. It gives both diagrams and drawings of a great number of valves and motions for same. There may probably be an English translation of same, but I have not seen one. When you ask for the methods used in setting the valves, I suppose you mean the practical way which will most probably vary to a certain extent in each shop you work in. I do not know of any book which treats of the subject. All books on valves give the position of the eccentric, or the method of obtaining it for the various valves treated of.—P. B. H.

**Mildewed Glass.**—T. W. (*Loughboro'*).—I am afraid you cannot restore your glass. Mildew is a fungus growth, and to destroy it would destroy the silvering. To re-silver, kindly refer to articles in WORK, Vol. II., No. 55, p. 44; No. 75, p. 373; No. 78, p. 422; No. 83, p. 503; and No. 85, p. 536.—W. E. D., JR.

**Aphengescope.**—G. S. R. (*Tewkesbury*).—The above instrument is not a patent, and you can make either of those which have been described in WORK.—C. A. P.

**Silvering Glass.**—MIRROR.—The formula you quote is generally, I believe, called "Drayton's Process," and is given correctly, except in one important particular. After you have floated on the glass a few drops of a mixture of oil of cloves and spirits of wine (in the proportion of oil of cloves one, spirits of wine three) should be dropped in different places, or diluted oil of cloves can be added to the solution before it is poured on the glass; the more oil of cloves the quicker the deposit, but do not add too much. To remove the old, if by quicksilver process, use wood naphtha on a rag and rub hard.—W. E. D., JR.

**Ferrotype Process.**—W. J. H. P. (*Cookstown*).—The ferrotype process is simply the wet collodion process on metal plates—ferrotype plates being thin sheet-iron covered with a dark varnish, usually of a chocolate tint, and may be purchased at the photographic dealers in dozen or gross packets of the sizes generally adopted for dry-plates. They may be trimmed with a pair of scissors to any shape. There is no special way of treatment differing from ordinary collodion positive work, and any collodion and developer that will work well on glass will do the same on ferrotype plates. Their advantages are in comparison with glass, less weight and liability to breakage; and the disadvantage is, not so true a surface, and the image is reversed, which is not of much importance with the class of work usually done on them. Of course, by aid of a mirror or reversing prism, the reversal might be remedied, but it rarely ever is.—D.

**Umbrella Materials.**—EYRE.—The following are the names and addresses of the firms in Liverpool and Manchester who sell all kinds of umbrella materials:—McKenzie Bros., Bold Street, Liverpool; W. Walmsley, Victoria Buildings, Victoria Street, Manchester; Hughes Young, Deansgate, Manchester.—W.

**Lady's Work-box.**—W. J. (*Portsea*).—Work-boxes offer very little opportunity for originality. As you intend it for a present, I advise you to make it diamond shape. Join each of the four large sides to the narrow sides as in plan (Fig. 3), the grooves, etc., extending from top to bottom. Great strength is not particularly necessary. It might answer if you screwed or dowelled a green-cloth covered bottom board into position. It will be preferable to make the reel and needle boxes bodily removable. Construct a shallow tray, and join three divisions across its width, and a desirable number of partitions between these. For firmness, tongue the ends of each cross-piece into the divisions it meets with. See back numbers for descriptions of these joints. There is a feature about the

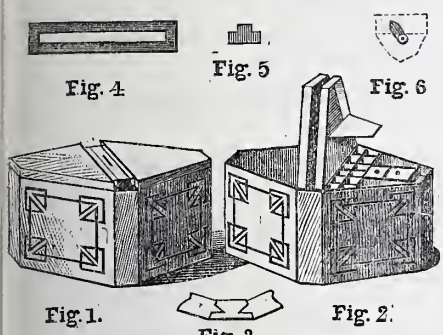

Fig. 4. Fig. 5. Fig. 6. Fig. 1. Fig. 2. Fig. 3.

Lady's Work Box.—Fig. 1.—Box Closed. Fig. 2.—Box Open. Fig. 3.—Plan of one Corner. Fig. 4.—Plan of fixed Top Board to which are hinged the Lids. Fig. 5.—Section of Removable Top Piece shown between the Lids in Fig. 1.—Fig. 6.—Fastening for the Flaps in Lids.

double lid which will not recommend it to an impatient lady. Mitre and screw four narrow pieces to a whole board. Fill the space of it partly up with a fixed board, and to it hinge a companion flap, the latter with a fastening (Fig. 6) attached. This makes one lid. A rail, in section like Fig. 5, is needed to retain the lids as in Fig. 1—nothing more, unless to provide against dishonesty. Have a fixed slotted rail (Fig. 4) across the top of the box, and screw two narrow pieces to the backs of the lids, as in Fig. 1, to enter the slot, and you will find that, by removing the cross-rail, the lids can be opened as in Fig. 2. In my limited space I cannot show how the ends of the removable cross-piece must be cut, nor the distance apart the lids must be hinged; but a little thought will make it all clear to you. Arrive at best size by cutting and arranging cardboard. Place in our hands another query concerning covering of small lids.—J. S.

**Rubber Stamps.**—A NEW SUBSCRIBER—Full directions for making rubber stamps are given on pages 594 and 630 of Nos. 38 and 40 of Vol. I. of WORK. Some modification of the process may meet your case, but evidently no suggestions can be given unless the specific purpose be clearly stated.—QUI VIVE.

**Imitation of Granite Stone.**—J. B. (*Devonport*).—This process is one of the minor and elementary divisions of the Art of Marbling. Space will not permit an exhaustive lesson here, but I give you a few concise directions which will probably serve your present purpose. For a staircase wall, either a pink or grey granite would suit—that is, assuming you require something "everlasting" and sanitary, and not a "modern" decorative treatment. Remember grey walls will give a cold sensation, pink a warm and cheerful effect. For the former, paint the walls with grey paint of a "leaden" hue; then, when dry, with a small piece of honeycomb sponge, apply the spots of pure black and white, and finish with a light varnish. For pink granite, mix your ground with white lead paint and a little Venetian red in oil. Put in the black and white spots as for grey. A skirting of "black and gold" marble beneath this would be best in your case. Banisters would look well and consistent if painted a deep bronze green, then coated with hard-drying varnish. Before this gets set, rub a little gold bronze-powder on the prominent parts with a little piece of unwashed wash-leather.—DECORATOR.

**Black Enamel.**—J. M. (*Wanstead*).—Slate mantel-pieces and similar goods are enamelled and stoved on the principle of Japanned ware. Hence it is an operation not suitable for a novice to attempt. "Aspinall's" is an enamel, doubtless, equal to the majority of largely used brands; but black enamels of this type, even if one has sufficient ability to make a good job of applying it, cannot be compared for wear to the proper process. Varnish-making firms prepare these enamels especially for stoving. The best result an amateur is likely to obtain on a flat surface of any size, would be by coating the article with one or two thin coats of finely-strained "dead black," made from ivory black ground in turps, a little oil varnish or Japan gold size to bind it, and then thinned to working consistency with turps. Use a flat camel-hair brush, and spread barely and quickly. When hard finish with two or more coats finest copal varnish. Parts near the fire should be coated with Brunswick black.—F. P.

**Model Electric Motor.**—W. G. C. (*Taunton*).—Your model motor is a very tiny affair indeed, only having an armature ⅜ in. by ⅜ in., and field magnets ⅜ in. square. Fill the armature with No. 32 silk covered copper wire, and wind as much of this wire as you can get in the fields. As you have not given me the full dimensions of the wire space at your command on the magnet cores and the armature, I cannot tell the quantity of wire you can get on the model. The replies are published only in "Shop" for the general benefit of all readers.—G. E. B.

**Books on Drawing, etc.**—L. G. (*Falmouth*). The following books may help you—"The Principles of Perspective" (Trobridge), 2s. 6d.; "Cassell's Course of Geometry," by E. A. Davidson, price 5s.; "First Book of Experimental Geometry," by Paul Bert, price 1s. 6d.

**A Squirrel's Cage.**—HUGH.—In making a cage for squirrels, or, in fact, a cage to keep any of the rodents or gnawing animals in, one thing has to be borne in mind, namely, keep the woodwork protected from teeth. The cage illustrated in Fig. 1 is made of ⅝ in. angle bar, zinc bottom and false bottom, the only wooden parts are the round discs for the wheel. These are of ½ in. mahogany, covered on the inside with tin. A small brass tube forms the bearings of the axle. The branch of a tree is not fixed to the bottom, but is suspended from the top,

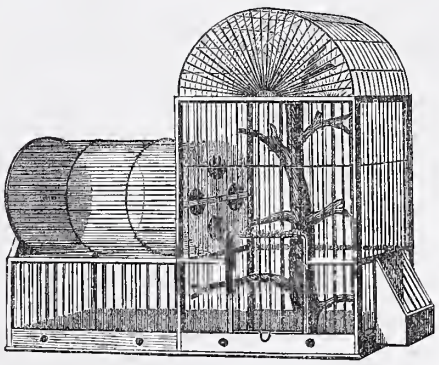

Fig. 1.—A Squirrel's Cage with Branch of Tree and Revolving Wheel.

and can be removed with a little trouble. The trays at the bottom are 1½ in. deep, and draw right out; and the compartment under the wheel can be made dark by a covering. The door opens upwards, and can be closed with a slam, or by its own weight if the fastener (Fig. 3) works easy. The top of the food-box opens and fastens in the same way as the

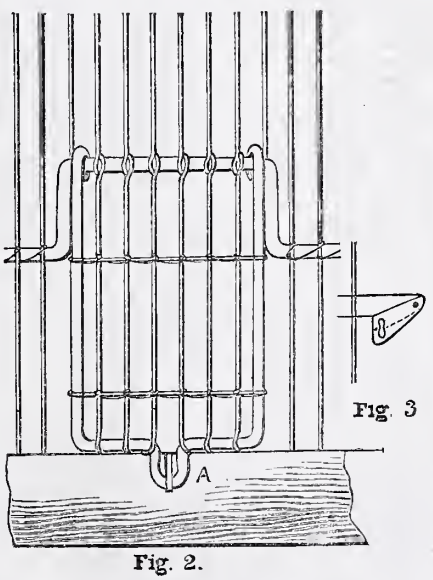

Fig. 3

Fig. 2.

Fig. 2.—Door for Fig. 1. Fig. 3.—Fastening for Door at A, Fig. 2.

door. I need not give full details of construction. I think a glance at the illustrations and the article on "Bird Cages," page 20, Vol. II., No. 54, will be quite sufficient.—F. H.

**Aquarium.**—F. W. B. (*Sunderland*).—The best book on the Aquarium is published by Upcott Gill, 170, Strand, W.C., price 1s.—C. M. W.

**Speculum Grinding.**—W. B. (*Bruntcliffe*).—Detailed notes on this subject will eventually appear in the ordinary columns of WORK. Meantime, I sufficiently answer your queries to enable you to go on. The rough edges may be taken off the glass disc either with an ordinary grindstone, using plenty of water, or with a lathe. In the latter case, cement a piece of wood to each face of the glass disc, and mount the whole in the lathe so that it runs true. Get a piece of soft sheet-iron about 18 in. by 3 in. Bend it as in Fig. 1, and clamp it by the part marked A to the tool-rest of the lathe. Bring it under the glass, as in Fig. 2. Feed sand, or coarse emery and water down in the direction of the arrow. The cutting substance will imbed in the soft iron, which will spring to the irregularities of the glass edge, but at the same time cut them away. As the edging approaches completion, the other end (C) of the iron band may be secured, and the disc may

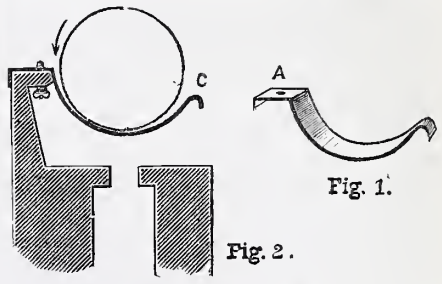

Fig. 1. Fig. 2.

Speculum Grinding.

then be easily cut to a perfect circle. Force nothing—do all easily. The only way to succeed in glass-grinding is to fully grasp the fact that the continuous removal of almost microscopic particles is the speediest and safest method of working. If the discs have been well chipped at the warehouse, and you are without a lathe, you might work your first experimental mirror unedged. For the rough grinding you need nothing but washed sand, or coarse emery and water. The best motion for the rough grinding is a straight stroke, which exposes one-third of the diameter of the lower disc at each stroke. Meantime the operator should walk continuously round the post or bench, and should also revolve the speculum disc under his hand. Let the straight stroke preponderate. Otherwise, an occasional systematic irregularity is an advantage. The time necessary to rough out a speculum will be from three to five hours continuous. Afterwards, the time necessary depends on the character of the work done. When you have roughed the disc out, or if you get into any difficulty, you must come to the editor again.—E. A. F.

**Fastening Glass Balls.**—F. K. B. (*London*).—There are several good cements in the market that you might use to fasten the glass balls to your looking glass, and the balls being ground flat on one side will greatly facilitate matters. You might use "Coagiline," warming both glass and balls as much as they will safely bear (in fact, making the articles hot enough is the great secret of success with all cements); or I can from experience recommend "Le Page's Liquid Glue," or, if it is likely to stand in a damp place, the following may be tried, as it is said to resist water. Dissolve ten parts of pure dry gelatine in a hundred parts of water, add ten parts of a concentrated solution of bichromate of potash, and keep in the dark. When used the light causes a chemical change to take place, and the film of cement becomes extremely tough and durable.—W. E. D., JNR.

**Opal Glass Letters.**—J. P. C. (*No Address*).—I do not know of any machine to cut out opal letters. Do you wish them like those sold? If so, they are not cut out; but seeing you wish to utilise the waste, I can only suggest that you make templates, and cut out with a diamond; but perhaps some other subscriber seeing this reply may be able to suggest a better method.—W. E. D., JNR.

**Triunial Lantern.**—L. J. K. (*Dublin*) wishes to know whether the lid of a piano ¼ in. thick would be sufficient substance for the body of the lantern described in WORK. Most certainly yes, as your piece of stuff is sure to be thoroughly well-seasoned. The issues in which the above articles appeared are Nos. 83, 87, 91, 96, and 100. You will also find additional information on lantern matters in the "Shop" columns of the above issues.—C. A. P.

**Safety Bicycle.**—A NEW SUBSCRIBER.—The numbers of WORK in which the articles on Safety Bicycles appeared are Nos. 107, 111, 115, 119. You can get these numbers of WORK through a newsagent, or of the publishers, Cassell & Co., London, E.C.

**Sign Writing and Lettering.**—W. S. M. (*Brixton Hill*).—The articles upon this subject will be found in the following numbers of WORK:—Nos. 1, 2, 4, 11, 13, 17, 19, 23, 30, 34, 39, 43, 44, 45, 47, 49, and 51. These and any other of the back numbers, together with the Indexes to Vols. I. and II., are procurable through any bookseller, or of the publishers, Cassell & Co., London, E.C.

**Sign Writing.**—N. H. (*Longley*).—We do not give the addresses of contributors. Any stamped and sealed communication forwarded here shall have the address completed and posted.

**Skiver Leather.**—J. H. B. (*Moseley*).—The term is as I have written it, not *skiva*. You ask for instructions for the preparing the above leather to blocck in imitation gold, and what varnish to use after. There are many methods by which this is done. Wash the leather over with paste-water, and afterwards give two coats of glaire, allowing the first coat to dry before applying the second. Lay on the gold in the usual manner, blocck, and wipe off. Another, wash the leather with glue-water, and, when dry, lay on the gold and blocck. Another, use dry powder, such as resin powdered, gum sandrac powdered, dust over the leather, lift the gold on the block, and block as usual. Afterwards varnish with shellace varnish or Zaehnsdorf's bookhinders' varnish, to be had from the maker—Cambridge Circus, Shaftesbury Avenue, London, W.C. In all of these methods, the press must be hot while blocking. For further information, see many back numbers from the first.—G. C.

**Phonograph.**—F. W. W. (*Hastings*).—I cannot give instructions in "Shop" for making wax cylinders for this instrument for several reasons, the chief being the want of space. The information would he of little use to you without drawings of moulding apparati. The cylinders are not made entirely of wax, but of a composition in which wax forms a part. In some forms we are informed that "wax is not in it!" There has been no article on the phonograph as yet in WORK.—W. D.

**Ash Bar Hole.**—T. M. G. (*Hoddesdon*).—Although I do not know the plan adopted hy the makers of gymnastic apparatus, yet I may say that the essential conditions are well known, namely, the boring tool must revolve, and the bar must revolve in the contrary direction. This at once indicates a lathe or similar contrivance. Were it not for the fact that the grain of the wood is likely to influence the direction of the bore, you might bore from both ends. I believe that with a Morse twist-bit, as modified by the co. for wood, you could venture to do so. If not, you will have to have lengtbening bars made to the boring tool up to 8 ft. long, and such tools are so special that, no doubt, you will have to have them made to order. Unless you expect to have many bars to bore, I should strongly advise obtaining the bar ready, which you may do of the gymnastic apparatus manufacturers.—B. A. B.

**Safety Bicycle Rims.**—CONSTANT READER.—Rims 30 in. by ¾ in. crescent, 3s. pair; hubs, plated and tapped for spokes, from 11s. to 21s. (The above are prices to the trade.) Price lists of tbe above, and all other materials and fittings, can he had of Brown Bros., 7, Great Eastern Street, London; also St. George's Cycle Company, Upper Street, Islington; also W. A. Lloyd & Co., Lionel Street, Birmingham.—A. S. P.

**Restoring Leather Chair Seats.**—ANXIOUS.—To re-dye worn and faded leather seats is, I believe, an operation which upholsterers admit that they have no satisfactory way of doing. When seats reach this stage, the only sound thing to do is, it is said, to give them new coverings. Something may, however, be done in the way of brightening up the faded material. White of egg will do this, or French polish ligbtly laid on so as not to saturate tbe leatber.—S. W.

**Patent.**—E. W. G. (*No Address*).—A person who has ohtained provisional protection for something, is simply assured tbercby that no *later* applicant can obtain the grant of a patent that will give him a prior right. The great danger in putting the invention before the public, prior to the patent heing scaled, is that there may be a provisional protection of earlier date for a similar thing, with a similar title, in force, and which may be wide enough to admit of what E. W. G. may sbow being included in the complete to follow such provisional, in which case E. W. G. would be nowhere, unless he could *prove* that the prior applicant had appropriated his invention, and that his provisional did not fairly comprise it. It is not needed in a provisional to give all the details that are absolutely essential in a complete, but merely such a general description as shall satisfy the examiners of the idcntity of the invention described in the complete. According to the "popular" idea, any inventor or intending patentee is at once qualified, having made an "invention," to know, understand, and carry out all the proceedings needed to obtain a sound and valid patent, in the right and proper manner required for this purpose. It is needless to assure E. W. G. that this—like most "popular" ideas—is very far from the truth; and we can only pity those who are foolish enough to be led away by such erroneous notions.—C. E.

**Repairing Barometer.**—MERCURY.—You did not go far wrong in your attempts to clean and refill the tube with mercury. Your difficulties arose more from want of practice and the knack acquired only through this, tban from mistakes in the process adopted. It is only when a tube appears to be smeared with mercury, and has a grey, metallic appearance inside, that is is necessary to clean it with dilute nitric acid. The acid should be diluted with distilled water, and the tube rinsed with distilled water. When this has heen done, and the water drained out, introduce a little pure alcohol and drain this out; then warm the tube carefully, beginning at the closed end, and drive out all traces of moisture with the last few drops of alcohol. The mercury, when dropped on a clean china plate, should run about in bright round globules without soiling the plate; if the drops drag, and leave a grey trail bebind them, the mercury is not pure, nor clean enough for the purpose. There should be no scum on the surface. The mercury should he filtered through fine pinholes made in chamois leather after it has heen cleaned and dried, unless it is pure and freshly distilled. After this, it should be heated in a glass beaker to expel the last trace of moisture before it is introduced into the warm tube. As the mercury has to expel air from tbe closed end of the tube, it must be introduced to this part drop by drop, so as to allow the air to escape. You did quite right in shaking the mercury in warm. The last traces of air are expelled by heating the closed end of the tube over a spirit lamp, and boiling the mercury, inch by inch, throughout the tube. The process will go on more smoothly as you acquire skill by experience.—G. E. B.

**Price of Dynamo Castings.**—AMATEUR.—Apply to Mr. S. Bottone, Wallington, Surrey, or to Mr. G. Bowron, 93, Praed Street, London, W., for price of 20 c.p. dynamo castings. You will get them as cheaply from those gentlemen as from any one else in the trade.—G. E. B.

**Brass Bearings.**—CARDIFF NO. 2.—Brass is not used by good engineers, or considered satisfactory for bearings. Gun-metal is the term applied to the compound used for this purpose, and in many cases the "brasses," as they are technically termed, are "bushed" or lined with white metal, such as what is known as "Babbitt's" metal, or other nearly similar compounds, and, if carefully looked after, are found to give very satisfactory results in practice. The production of bearings for machinery of the required hardness is obtained hy the materials used for the purpose and the proportions employed of each. Gun-metal may be made of the following materials in or about the following porportions: Bristol brass, 112 lbs.; zinc, 14 lbs,; tin, 7 lbs.; taking care to put in tbe most fusible of the metals last. Common brass used for casting consists of 20 lbs. copper, 1¼ lbs. zinc, 2½ lbs. of tin. Yellow brass is made by melting 30 lbs. zinc with 70 lbs. copper. Hard brass for casting consists of 25 parts copper, 2 parts of zinc, and 4½ of tin. Yellow brass for turning is made of 20 parts of copper, 10 parts of zinc, and 1 to 5 ozs. of lead, which is the best metal put into the pot. Ordinary "pot" metal is made of 3 parts of lead added to 8 of copper. White metal s made by melting 24 lbs. zinc, 4 lbs. copper, 8 lbs. antimony; and, when these proportions are melted add 72 lbs. tin.—C. E.

## III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Chuck.**—IGNORAMUS wishes to know the best and cheapest way to go to work to make an oval chuck for wood turning in an 8 in. lathe.

**Hair Oil.**—X. Y. Z.—Could any reader give me a recipe for making a good cheap hair oil for sale?

**Bread Cutter.**—JEAN writes:—"Will any of our readers kindly tell me bow to make a loaf-slicing macbine?"

## IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Xylonite.**—L. S. M. (*Bishop Auckland*) writes in reply to BEAVERSTOWN (see page 286):—"I have got this in small quantities from C. F. Mearing, 33, Sidmouth Street, Gray's Inn Road, London. If he does not now supply it, you can get it through a chemist."

**Glacial Decorations.**—M. (*Bishop Auckland*) writes in reply to J. H. (*Salford*) (see page 286):—"I have removed these by sponging with hot water, and scraping them off. They will require a little time to soften."

**Camera.**—R. M. (*London, S.E.*) writes, in reply to BOY SORTER (see p. 206, No. 117, Vol. III.):—"I would advise BOY SORTER to invest in a Lancaster's 'Mervcilleux' camera set, at 21s. This is the best value for the money I know of, the set being well turned out, and consisting of camera, slide, excellent achromatic lens, and stand with brass top. To get anything cheaper than this would be false economy. (2) I can recommend Hepworth's "Photography for Amateurs" (Cassell & Co., Ltd.) and "Burton's Modern Photography" (Piper & Carter). Both books are published at one shilling. For a beginner the former is, perhaps, the better, as, besides being very lucidly written, technical terms are avoided. (3) As to what are the best dry plates, opinions may differ. Personally, I use Ilford's, and am very satisfied with them."

**Sealing Wax.**—M. (*Bishop Auckland*) writes, in reply to J. C. (*Chelsea*) (see p. 206, No. 117, Vol. III.):—"This is made by melting together four parts of white or bleached shellac, one part of Venice turpentine, and one part (or more, if required) of white lead. Stir well together, and when melted, roll upon a marble slab (heated underneath) with a picce of hard wood till nearly of the right size, and finish by rolling between two marble slabs (cold). To polish the outside, slowly turn the sticks between two charcoal fires till the outside melts. For square or oval shapes, cast the wax in steel moulds."

## V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—T. L. (*Lincoln*); F. M. (*Portsea*); W. J. E. (*Salford*); A. E. S. (*Wootton Bassett*); C. T. (*Edinburgh*); REARER; T. J. S. (*Durham*); S. T. (*Sevenoaks*); H. F. B. (*Barking*); STENCIL; MICRO; J. M. (*Hebburn-on-Tyne*); C. T. (*Edinburgh*); A. R. (*Scorrier*); J. W. (*York*); J. S. (*Pimlico*); A WOULD-BE DECORATOR; H. H. (*Finsbury, E.C.*); C. C. E. (*Lincoln*); CURVE; YOUNG; F. M. (*Portsmouth*); H. B. (*London, W.*); T. R. B. (*Blaydon-on-Tyne*); C. & M. (*London, N.*); PHOTOGRAPH; E. T. (*Handsworth*); J. T. S. (*Sheffield*); J. A. S. (*Enfield*); J. O. H. (*Wandsworth*).

# A WONDERFUL MEDICINE.

# BEECHAM'S PILLS

Are universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, and all Nervous and Trembling Sensations, &c. &c. The first dose will give relief in twenty minutes. This is no fiction, for they have done it in countless cases. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

**Worth a Guinea a Box.**

FOR FEMALES THESE PILLS ARE

"A priceless boon, a treasure more than wealth; the banisher of pain, the key to health."

These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the nervous and debilitated is,

***BEECHAM'S PILLS have the Largest Sale of any Patent Medicine in the World.***

Prepared only by the Proprietor, T. BEECHAM, St. Helen's, Lancashire, in Boxes 9½d., 1s. 1½d., and 2s. 9d. each. Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

## AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the maximum of efficiency, combined with the minimum of cost. This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their **Improved Eclipse Cameras and Outfits**, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above: also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra. These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.,** post free.

*A Wholesale Dealer's Stock-in-Trade at about Half-Price.*

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

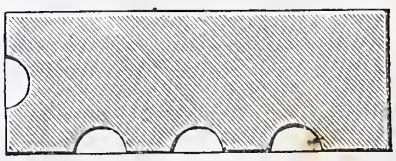

Fig. 5.—Section of Uprights (full size).

## A WHATNOT FOR AMATEURS.

BY H. J. MARK.

INTRODUCTION—JOINTING—UPRIGHTS—SHELVES—BACK-PIECE—ENAMELLING—FINAL REMARKS.

*Introduction.*—In submitting to the readers of WORK this simple, yet useful, little article of furniture, I do not do so claiming for it any special merit, as I am but an amateur myself. It is my own design, easy to make, and fills a corner very effectively. To those who, like myself, are not yet so far

advanced as to be able to tackle a hall-stand or bookcase, it may prove useful as a study, if only in the use of the square.

It is made entirely of deal, and finished in two colours of enamel and gold paint. Other woods, of course, might be used, setting aside the enamel and gold, but it would then become more expensive, and expense is a thing we have all more or less to study.

It must be borne in mind that the wood should in all cases be quite dry before working, as if used in a damp state, twists and warps will soon set in, and the work be spoilt. I make it a rule to keep my wood in the house some weeks before using; and by buying it a bit every now and again, I have always a dry piece ready to go on with.

*Jointing.*—In adopting the manner of jointing shown in Fig. 6, I have done so for the following reasons:—

(1) As I live in apartments, I must make my furniture so as I can take it to pieces readily for packing purposes. (2) As each piece is enamelled more easily and better by being done separately than if done when fitted up and put together.

As a consequence, I have not used any glue, and as stability is the main thing to be desired, I consider my method to be the best; glue is a messy substance at all times, and unreliable as a joint unless applied by practical workmen. And I consider that if more screws were used in putting together our modern furniture, and less glue, we should have far stronger articles for our money.

For all the joints out of sight I have used $1\frac{1}{4}$ in. screws; for the joints in front I have used fancy brass-headed $1\frac{1}{4}$ in. nails, as shown in Figs. 1 and 4. In driving in the nails the head of the hammer should be covered with a piece of soft leather for the protection of the brass heads. The bare hammer will flatten and scratch them, and spoil their appearance.

*Uprights.*—The uprights are $\frac{3}{4}$ in. thick, and, of course, cut out of one piece of stuff, taking care to allow for the recessing into the shelves. All the recesses need not be more than $\frac{3}{16}$ in. deep. The heads and two feet I shaped out with a fret saw, the speckled portions shown in Fig. 4 being a little diaper work punched over. The grooves are all cut with a $\frac{1}{4}$ in. gouge: at least, that is the way I have cut mine, but those who have a suitable plane or "scratch" could, of course, use it to advantage. After cutting the grooves, to get them smooth I rounded off a piece of wood to fit them loosely, and by its aid and sand-paper rubbed them down. Fig. 5 is a full-size section from which the gauge may be set for marking them out.

*Shelves.*—Fig. 3 is a plan giving sizes of shelves ($1\frac{1}{2}$ in. scale), the two bottom ones being of the same size. These can also be set out on and cut from one piece of stuff, and are $\frac{1}{2}$ in. thick, taking care as before to allow for recessing into back-piece, the grooves on their front edges being worked the same as for the uprights. They are recessed into uprights as well, care being taken to get the uprights perfectly square within the shelves, or when put together they will stand lop-sided.

*Back-piece.*—The back-piece is a triangular piece of wood, as shown in plan, 4 ft. long, and with a 2 in. face, the two sides forming a right angle, so as to fit the corner of a room. The head-piece I have not diapered, as it would be hidden by a vase, etc. For the same reason I have not shaped the foot.

*Enamelling.*—After having fitted the whole together, taken to pieces, and thoroughly sand-papered the parts, give a coat of size and whiting mixed as a filling; when dry, sand-paper again, and proceed to enamel. I use about three dessert-spoonfuls of whiting to half a pint of weak size. All the grooves, with the exception of the middle ones of the uprights, are coloured in turquoise blue. The middle ones, together with the diaper work, are worked in gold paint; the rest of the whatnot is done in Arabian brown. Two coats of each is sufficient. I have used Blundell, Spence & Co.'s enamel and gold paint, and find it very good; I prefer it to others, as it dries with a higher gloss.

*Final Remarks.*—If nicely finished, with one or two vases and like ornaments placed upon it, it will, I am sure, give satisfaction. On my own whatnot I have hand-painted flowers, etc. The enamel colours may be left to one's own taste and inclination; those I have chosen look well, the blue contrasting nicely with the rich brown, and the gold giving a very finished and artistic appearance.

A further improvement might be made by converting the middle portion into a cupboard with folding doors, having either carved, fret, or painted panels. For instance, the two panels of the iris and narcissus by Mr. Gleeson-White (see WORK, No. 60, page 125); or gesso-work might be utilised.

One word more: don't be afraid of using the square too much. It is a maxim that an old friend of mine, a carpenter, gave me, and one by which I have profited.

## NOTES ON SAW SETTING.

BY M. POWIS BALE, M.I.M.E., A.M.I.C.E.,
*Author of "Wood-working Machinery," "Saw-Mills," "A Handbook for Steam Users," &c.*

SWAGE SETTING—SPRING SETTING—HAMMER SETTING.

IN very few things is there more difference of opinion than in sharpening and setting saws. On the present occasion I propose to discuss briefly the different methods of setting, noticing some of the advantages and disadvantages of each method.

*Swage Setting.*—Swage setting—called also "upsetting," "jumping," and "spreading"—is more largely practised in America than in this country. In this case clearance is obtained for the saw by widening the points of the teeth, usually by means of a crotch punch arranged with two V notches, which are driven on to the points of the teeth by a hammer or weight. The second notch in the punch is rounded, and spreads the teeth points out. We think this plan, especially for circular saws of stout gauge, has much to commend it, more especially if the wood is cross-grained and knotty, as swaged teeth will stand up to the work, while spring-set teeth are apt to dodge the knots. Swaged-set teeth will also stand a quicker feed than spring-set, all things being equal; they, however, take more power to drive—probably about 20 per cent.—and unless the setting is carefully done ridge marks are left on the log. I think swage setting is, on the whole, more adapted for soft than hard wood.

It is claimed by the users of swaged-set teeth that swaging condenses and hardens the steel at the points of the teeth: but if this is so, with saws correctly tempered it would, I take it, be likely to be detrimental, and cause the points to crumble. Another trouble found in swage setting is the difficulty of getting perfect uniformity of set, without which no saw can be pronounced to be in first-rate cutting condition. Swage setting does not sharpen the teeth of the saw, as some may suppose.

When a saw is set or spread by means of a punch and a blow from a hammer, care should be taken that the points of the teeth only are spread, and that the tooth itself is not bent or strained, and that the blow given and the hammer used are not too heavy. The teeth should be carefully tried with a straight-edge on both sides and points, and be exactly in line. In swage setting, should a tooth point be broken by striking a nail, it can be lengthened slightly by raising the punch or swage when in the act of setting the tooth, and the point of the tooth will be upraised, and, if not too much broken, will take its share of duty with the rest.*

To "spread" set all the teeth as nearly as possible alike with a crotch punch, it is necessary to regulate to a nicety the weight or strength of the blow given by the hammer. In America a tool has been introduced to do this mechanically. It consists, briefly, in mounting the crotch punch on the end of a tube or rod, and arranging a series of movable weights, with holes through them, to slide up and down the rod. These weights are allowed to drop on the punch, the strength of the blow being regulated according to the gauge of the saw and the amount of set required. For saws of large diameter and thick gauge spread set can be recommended, as it is very difficult to spring set or bend the teeth of a thick saw with regularity.

*Spring Setting.*—This is perhaps the most general kind of setting, and, if regularly and carefully done, answers very well; the teeth, however, have a constant tendency to assume their original position. Saw teeth should not, under any circumstances, be set without a gauge, as it is a wasteful and stupid plan, producing rough work, and more rapidly wearing out the teeth which happen to be overset. In practice it will be found that a saw perfectly set will work much freer, cut smoother, and, at the same time, will waste less wood than an imperfectly set one; less set is also required on a truly and equally set saw to effect the desired clearance.

Several good mechanical saw sets, combined with gauges, are now made, and so arranged that when they are fixed to any desired set it is impossible to overset a tooth; consequently, the teeth are all set exactly alike, and, if they are equal in length, each tooth gets its fair share of work, the friction of working and waste of wood being reduced to a minimum. In working, it is found that the teeth of a saw wear at the side of the points, and if some teeth have more set than others, these are unduly strained, and, from the severe and uneven friction, are often heated, and are inclined to buckle and run from the line. In using spring set, it is necessary to somewhat overset the saw, to compensate for the tendency of the teeth, especially when worn or dull, to spring back to their original position.

I have recently seen a very neat form of American tool for spring setting by means of a cam-lever, by which a very even set may be obtained without unduly straining the saw teeth. The operator stands behind the saw, and the set is attached to the

* See "Saw Mills; their Arrangement and Management," by M. Powis Bale.

eth by placing a bed die on the point the tooth to be set, so that the point will oject beyond the die about one-sixteenth an inch; the cam-lever is then brought wn to a stop on the cam, at the same ne bending the teeth towards the latter. four-point gauge is fitted to the lever, d it can be adjusted to any amount of set sired by means of a thumbscrew. It is imed as an advantage of this arrange- nt that the bending power is exercised the tooth between two bed bearings, that the operator has only to bear down the cam-lever, and the more power applies the tighter he fastens the set the saw; and, at the same time, the bend a curve and not an angle, and that, erefore, the saw teeth are less liable to cture.

If a saw is allowed to get dull it will ring from the work, and increased power ll be required to force it through the od.

*Hammer Setting.*—The third system of ting I have to notice is hammer setting. e old-fashioned way of doing this was th a punch and a block of wood, and very brutal way it was, as it strained saw-plate, and sometimes broke the th; at the same time, it was impossible get the teeth to one uniform set, con- quently the timber was scored, and much wer consumed unnecessarily. If carefully l judiciously done, hammer-set saws will nd up well to their work. The best plan th which I am acquainted is to mount saw horizontally on a conical centre, l allow the teeth to rest on an adjustable el die made with a bevel edge turned entric, so as to allow of the right pro- tion of set for teeth of various sizes. th this arrangement any desired amount uniform set can be given to the teeth hout unduly straining them or the saw- te. Hammer setting is a fair test as to quality of the saw, as the teeth may ck or fracture if the steel is burnt or oo hard a temper, or bend readily if too t.

n conclusion, it must be borne in mind t whatever kind of setting is employed, successful and economical working *abso- e uniformity* is imperatively necessary. his is not secured, the work turned out of inferior quality, and wood and power wasted. It should also be remembered t setting does not increase the cutting ver of a saw, as a saw will cut faster h little or no set, provided the nature of wood will allow it to pass through with- binding. The amount of set required, refore, should be carefully judged by the yer, and no more set employed than absolutely necessary. For instance, in ring wet wood a sharp saw and a fair ount of set are required, whilst for hard otty wood very little set should be used.

## ACTICAL PAPERS FOR SMITHS.

BY J. H.

### PUNCHING AND DRIFTING.

the moulder cores holes in his work order to avoid altogether, or to en, subsequent labour, so the smith iches and drifts rough holes in his work the same purpose. Punching, drifting, l drilling are the three methods by ich holes are commonly made in the ithy. The first two are performed on red- iron and steel; the last, and sometimes second also, on cold metal. The present article will deal only with punching and drifting.

Iron and mild steel will stand punching to an extent that would be impossible in a crystalline material like cast iron. For much work punching makes a clean, finished hole, to which nothing is done subsequently, and is quite good enough for its purpose. In other cases, punching, like the coring of castings, takes out the bulk of the metal, leaving a certain small allowance for finishing with drill, rymer, or boring tool. Generally the details of the process of punching are as follows:—

The iron to be punched, being brought to a suitable full red or white heat, is laid across the anvil, and the punch (Fig. 12) is driven about half-way through by means of the sledge or hand hammer, from one or two to several blows being required, depending on the thickness of the material. The punch is then withdrawn, and the iron is turned over and laid upon its opposite face. A dark spot indicates where the chilling effect of the punch has taken place, and enables the smith to set the punch again in position for piercing the supplementary portion of the hole. The tool is then driven through—the holes meeting. During the formation of the second portion, the work is either laid upon a bolster of the form shown in Fig. 13, or over the hole in the anvil, and the punch then passes freely through.

If the hole is deep, the hot iron closes and tightens around the punch, and the latter is therefore withdrawn at every three or four blows. Further, the heat of the iron is communicated to the punch, and makes the latter very hot, so that after every three or four, or half dozen, blows, it is necessary to dip the punch in water to cool it.

These punches are made circular, square, oval, oblong, and wedge-shape in cross section. They are handled with hazel or iron rods, or with rigid wooden handles passing through eyes.

The methods of producing punched holes are varied according to circumstances. If it is desired to preserve the same, or nearly the same, amount of metal all around the hole, the hole is not punched absolutely, but partly punched and partly drifted or opened out. Obviously, when a hole is punched entirely with a blunt-pointed tool, like Fig. 12, the amount of metal removed is equal in area to the area of the point of the punch itself, and the width of the bar will not be perceptibly increased (Fig. 14).

But there is another way of making a hole without weakening the bar to any great extent. A conical punch—that is, one tapered down nearly to a point—may be inserted, and the hole be formed and opened without the removal of any appreciable quantity of material. Or if a hot set is driven into the bar half-way through from one side and half-way across the other (Fig. 15), then a punch or drift can be driven in afterwards, and the slit opened out into circular or oblong form, as may be required, and the metal on each side thrust outwards, the full area being retained, save and except only that due to the stretching of the metal. This is often done.

Thus, for example, take long slot-holes. These are cut in two ways. In one, holes are punched at each end of the intended slot equal to its width, and the metal between is cut out with the hot set, cutting from opposite sides in succession, the cuts meeting in the middle (Fig. 16). In the other case, holes are punched at each end, and a chisel cut put down the centre from hole to hole, and a drift inserted and the metal opened out (Fig. 17). In this way the flanking metal is thrust out sideways, and the bulk of its section retained. Such a slot-hole is finished by the insertion in the hole of a drift or mandrel of the correct section, and the hammering of the outside edges of the bar upon it.

When punching holes, it is necessary to take account of the direction of the fibre—a matter treated of in the last volume of WORK. Unless attention is given to this, the iron will become divided instead of spread out. In any case, punching puts considerable tension on the fibres around the hole, with reduction of area, and it is an operation, therefore, that requires to be done with judgment.

To punch slotted cottar ways in which the section of the iron is not enlarged, take a tapered oblong punch or drift of steel, like that shown at Fig. 18, A, with rounding ends. Raise to a welding heat, and properly support the iron, according to its shape, upon a bolster or upon a bottom tool, and drive the punch half-way into it. Turn the iron over, cool the punch in water, and drive it in exactly opposite to the first position until the openings meet at the centre of the bar. Since the punch is tapered slightly, the hole is doubly tapered. It is also rough. A parallel drift or filling-piece is then taken and driven into the hole. The outside of the iron is then smoothed and finished, and the hole accommodates itself to the form of the filling-piece. When the shape is completed the filling-piece is driven out. This method of finishing hollow work while a central punch, drift, filling-in piece, or mandrel remains in *situ* is one adopted in many classes of work.

Fig. 18 illustrates the punching a hole through a stout pin. The pin selected for this example is 3¼ in. diameter, and the hole measures 1½ in. by ½ in., and it is made at one heat. The punch is shown at A. Its body below the handle is about 6 in. long, and well tapered. The bar being brought to a white heat, the punch is driven from one side almost, but not quite, through. It is driven so far that the position of the hole when it nears the opposite side to that from which the punch is driven is indicated by a darker colour of the iron. Then the pin is turned over and the punch driven into that darker spot, and the hole completed. Of course, during the punching of the hole from one side nearly through to the other the tool has to be removed several times, from four to half a dozen, and cooled in water. Further, it is not so easy to make a deep hole in a stout circular bar as it is in a thin flat bar, and the smith has to look out to prevent the hole from running to one side, and to indicate to the strikers in which direction they are to apply their blows. Moreover, two strikers are necessary to get a hole through this depth at one heat.

At the first stage of making the hole, the pin lies upon an ordinary bottom swage. At the second stage it lies upon a bolster, B, in form like a hollow swage, but pierced with a central hole, through which the drift can find a clear way.

When the hole is thus roughly punched, the metal around it will be partly compressed, partly bulged; very little, not one-sixth, perhaps, is actually driven out and removed by the punch. The bulging of the bar is corrected by hammering between top and bottom swages, and then the hole is

finished by drifting, all being done during the one heat. The drift is shown in Fig. 19. It is slightly tapered. A few blows of the hammer are sufficient to send it through the hole, opening it out. It is driven from each side in turn, and in this way the hole is made practically parallel.

During the punching of the hole, whenever the punch is withdrawn to be cooled, the hammerman strews a little small coal in the punched hole. This burns up gas which would otherwise offer much resistance to the passage of the punch.

Holes that are punched smaller than the finished dimensions are, when not intended to be machined, almost invariably finished with drifts. These are tapered or parallel tools, whose cross sections are those of the finished holes — circular, square, oblong, elliptical, or polygonal in form. The drifts are smooth, and being driven through the punched holes while red-hot, both enlarge and smooth them. Two drifts are often employed: a first one with considerable taper lengthwise, for the purpose mainly of enlarging the punched hole; a second with the merest trace of taper, for imparting the precise finished dimensions. The latter is then called a filler, or filling-in piece, or mandrel.

There are several forms of drifts. When we speak of drifts, the boiler-maker's drift is not included. The function of that tool is the pulling of the punched holes in plates into line. The tool is very slightly conical in form, and being driven through overlapping holes in contiguous plates, it thus brings those holes into line by the stretching of the plates, and so permits the rivets to pass through. The blacksmith's opening or non-cutting drift is used not for the same purpose, but in like fashion, its object being the enlarging of holes in hot metal.

Drifting may thus mean either one of two operations. It may mean the simple opening out by internal pressure of a hole already punched by means of a smooth punch-like tool; or it may mean the cutting and shaping of a punched hole to a finished and accurate form by means of a serrated tool.

In each case, drifts, like the punches, may be of any cross section—circular, oval, square, oblong, rhomboidal, parallel, or tapered, to suit the work in hand, and there is scarcely a limit to the forms in which they can be made and used. In each case the main idea is to save more expensive machine work.

In consequence of the modern improvements in metal-working machines, the value of drifts as shaping tools has much diminished. Thirty or forty years ago they were very much used, and are even now in many country shops and smithies. There are many small shops in which there is no slotting machine, and in these the drift is still one of the most serviceable substitutes.

Smooth drifts are rarely or never perfectly parallel, because the shrinkage of the forging around a parallel drift would render its withdrawal from the hole a matter of difficulty. In any case, the sides should subtend angles of not less than from two to four degrees. Not that a smith measures such an angle; he simply judges by the eye, or perhaps tests with callipers, the slight amount of taper given.

The cutting drift partakes either of the nature of a sharp punch or of a file. It does not open out by tension, but removes material from a roughly-punched hole. It will not remove a large quantity of material at once, but merely smooths and finishes a hole already nearly to shape and size. Fig. 20 shows a drift of the first kind, and Fig. 21 one of the second. The first is suited to shallow holes, the second to those of considerable depth; they are shaped with files from suitable blanks, and then tempered to a plum colour, or the colour between a brown and a purple. Obviously, the cross sections of these drifts may differ to any extent to suit any class of work. For fine work the teeth of the serrated drifts are set closer together; for coarse rough work they are spaced farther apart. They are bevelled to allow clearance for the chips, being the equivalent of backing-off in other cutting tools. For hard metal the angle between the cutting edge and the face is greater than for softer metals, thus following the practice in all cutting tools.

Oil should be supplied to the edges of the drift and of the hole when driving it in, and the work should be bedded firmly on a block of metal. Care must be taken that the drift is driven straight, as it is apt to run to one side—a tendency to be corrected by driving it in the opposite direction. If the hole is deep, the drift must be withdrawn once or twice for clearance of chips, or to remove excess of metal by chipping.

If the hole to be drifted is much smaller than the finished size, it will be necessary to enlarge it by chipping in such parts as may require enlargement.

The serrated drifts are used for making round holes square, round holes oval, round holes hexagonal, and so on. It is better in these cases to work one half the hole at a time than to endeavour to cut on all sides at once. Thus in cutting a square hole from a round one, one-half the drilled hole would be filled up with a half-round bit, and a flat drift operated against the other half of the hole little by little, thin backings being interposed one after the other. When one-half was shaped it would be filled up and the other half treated similarly. An oval hole would be shaped in the same way.

The drift is serviceable not only for thoroughfare holes, but for holes that do not pass right through their material. It is difficult to shape such holes by any other means than with a drift. And with a drift any number of holes can be smoothed and finished all alike. Taking, for example, a rectangular hole to be smoothed in one direction, the drift in Fig. 22 could be used. The face, A, would remove a thin shaving. To take a second cut, a thin strip of metal would be placed behind the drift; to take a third cut, another thin strip; and so on.

Cutting drifts are also used for finishing edges of work, such as the teeth of wheels, ratchets, etc. In this case the resistance is obtained by means of a strap-like fitting attached outside the work, against which face the back of the drift slides.

## WHEATSTONE METRE BRIDGE.

BY H. A. MILES.

USUAL FORM OF BRIDGE—PRINCIPLE—EXPLANATION—MATERIALS—DIMENSIONS OF PARTS—THE SCALE—METHOD OF DIVIDING—THE WIRE, BEST METAL—GAUGE—COMPLETION OF BRIDGE—EXAMPLE OF USE—DESCRIPTION OF MORE ACCURATE FORM OF BRIDGE.

*sual Form of Wheatstone Bridge.*—The Wheatstone Bridge" or "Balance," if ade in the form of a number of coils of ie wire of varying resistances, is a job ther outside the ability of the average nateur to construct; moreover, a certain nount of apparatus is indispensable, as a heatstone Bridge and Bridge Galvanoeter are absolutely necessary, in order that ie resistances of the coils may be accutely determined. The principle on which ie bridge is based is shown in Fig. 1. The Bridge," is shown by Fig. 3, and the parts are lettered, so as to correspond with the preceding illustration: A is a known resistance, D is the line to be tested, B C is a fine German-silver or platinum wire stretched between the two brass ends. The galvanometer is connected to the middle brass strip and to the German-silver wire, the exact point at which the contact is made being found by trial, and being the point at which no current passes through the galvanometer; then the two sides of the German-silver wire bear the same relation to each other as the known to the unknown resistance.

*Materials.*—The material used for the base may be of pine or any other wood, mahogany being preferable. The length will depend on the size of the scale. If this is a metre in length, the base should be fully 44 in. There is, however, no necessity for the scale to be exactly a metre long, as any length each end and holes drilled, both for screwing to the base and to receive the terminals. They should next be polished up, and lacquered with pale gold lacquer. The two short pieces should now be screwed down to the base, exactly 24 in. apart, and the long piece screwed on near the back edge.

*Dividing the Scale.*—To construct the scale, take a strip of cardboard, 25 in. long, leaving $\frac{1}{2}$ in. at each end of the scale to be gripped under the brass strips. The 24 in. should be accurately divided into a certain number of equal parts—five hundred will do very well—and numbered from each end, as shown in Fig. 4, which represents a portion of the scale. The divisions may be obtained by the method illustrated in Fig. 5, two lines being set out at similar angles from opposite ends of the given line, one above and the other below. If these are now divided into the

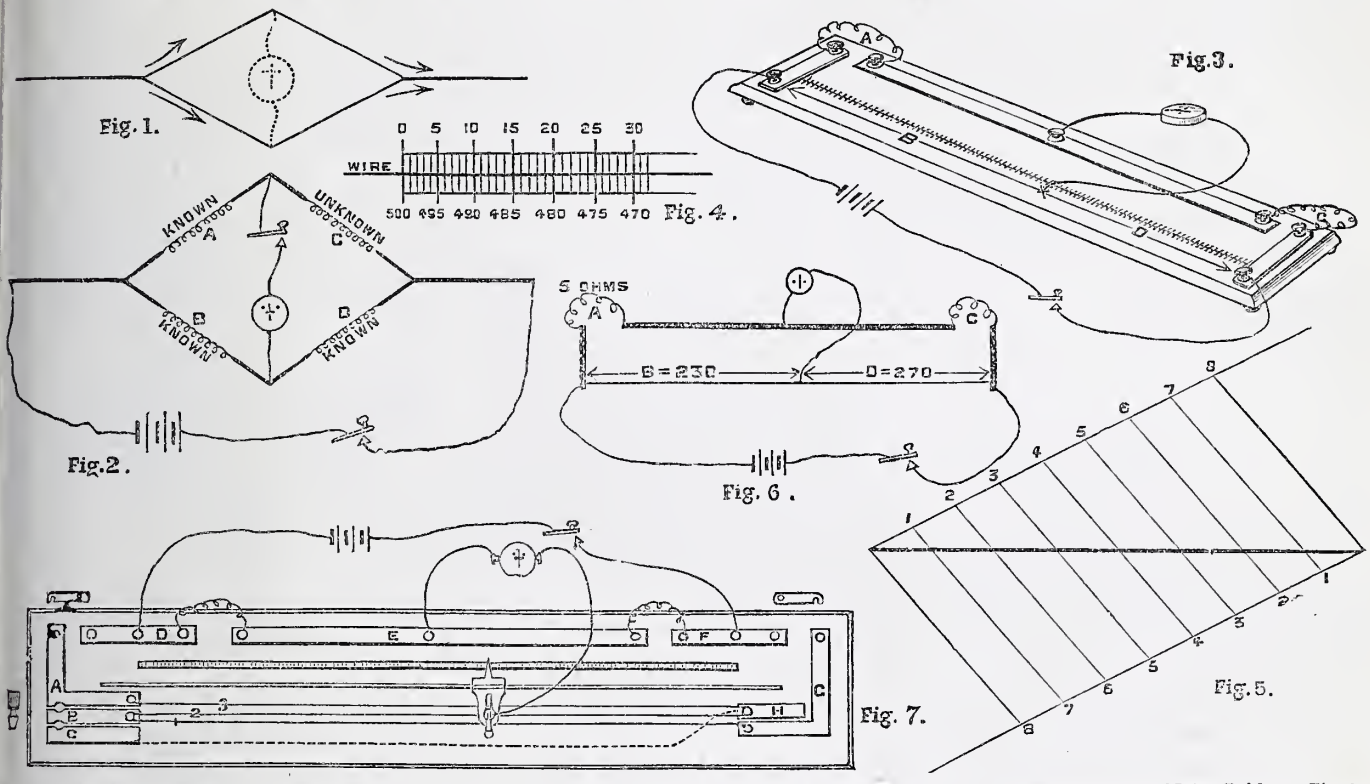

Fig. 1.—Diagram showing Principle on which Bridge is based. Fig. 2.—Method of testing Resistance. Fig. 3.—The Wheatstone Metre Bridge. Fig. 4.—Mode of graduating Scale. Fig. 5.—Mode of obtaining Accurate Divisions. Fig. 6.—Diagram illustrative of Example given of Use of Bridge. Fig. 7.—A better and more elaborate Form of Wheatstone Metre Bridge.

rrows denote the direction of the current lowing through the conductor, which is so livided as to offer two paths between certain oints. If the resistance of the two paths s alike, an equal proportion of current will low through each; and if a galvanometer e introduced between the arms (as shown y the dotted lines), no deflection would be bserved. If, however, one arm offered a greater resistance than the other, there would at once be a fall of potential, and a current would flow between the two arms hrough the galvanometer; and the deflection obtained would depend upon the amount f difference between the two.

*Principle.*—If the arrangement just described is still retained, adjustable resistances inserted in three of the arms, and the wire to be tested used as the fourth arm, it will be a simple matter to ascertain its resistance by varying that in the other arms until the needle stands at zero. (*See* Fig. 2.)

*Explanation.*—The design it is proposed to construct, generally called the "Metre can be equally divided into the requisite number of parts, but the longer the wire is the less liability is there for errors to arise. As a more complicated design is described later on for those who desire a better article, it is thought that the present one may be made with a 24 in. scale. Should anyone, however, wish to make it full size, no difficulty will be found in altering the dimensions to suit.

*Dimensions of Parts.*—Let us, then, start with the data necessary for a bridge with a 24 in. scale. The base will be 28 in. long, 4 in. wide, and $\frac{3}{4}$ in. thick. This should be planed up square, and a neat moulding worked all round the edge. A small turned knob may be fastened on under each corner as feet, and the whole French-polished or sized and varnished.

Some rolled copper or brass strip should now be obtained, a good size being $\frac{5}{8}$ in. by $\frac{3}{16}$ in. Two pieces 3 in. long (one for each end) and another piece 22 in. long will be required. These should be squared up at required number of parts to any convenient size, and parallels drawn as shown, the intersections of the horizontal line will be the required divisions.

When finished, the scale should be sized and varnished, colourless materials being used, after which it may be glued down to the base between the two brass ends, which should be temporarily removed. A better job may be made of it by cutting a shallow groove in the base, and thus sinking the scale in flush with the polished surface of the base. If this is not done, it will be necessary to scrape off most of the polish from below, to aid the glue in securing a good hold. A couple of small brass nails should now be hammered in the base, one at each end, under where the brass strips are fastened, and in such a position that a piece of wire stretched from one to the other would lie exactly in the centre of the scale. (*See* Fig. 4.)

*Wire—Best Metal—Gauge.*—The wire, which is preferably of platinum or platinoid,

though German silver does very well, is of No. 30 gauge, and should now be strained across from one nail to the other, bound round two or three times, and the nails then hammered in nearly flush. The brass ends may now be replaced and screwed tightly down, so as to ensure good contact with the wire. The terminals may be screwed into position, and the bridge will be complete.

*Example of Use.*—An example of its use is given here. A coil of wire, known to offer a resistance of, say, 5 ohms, is inserted at A, and the unknown length at C; then $C = \frac{D}{B} \times A = \frac{270}{230} \times 5 = 5{\cdot}85^{\omega}$, as shown in Fig. 6.

The bridge just described is of the simplest form. I shall now briefly show how a better one may be made on the same general principles. This is shown in Fig. 7.

*Description of a more Accurate Form of Bridge.*—In this case the scale had best be a metre in length, and divided into one thousand parts, additional facility for accuracy being given by the use of three wires and the insertion (if desired) of additional resistances, to increase the delicacy of the test.

The scale in this instance is more to the back of the board, and in front of it is a stiff brass rod, insulated, on which slides a wooden or ebonite key with a knife-edge contact point and an index pointer, both in line at right angles to the scale, so that the pointer indicates on the scale the exact point at which the contact is made. The contact point is adjustable, sliding in a groove, so as to touch either of the three wires as required.

For ordinary use the short-circuiting straps are kept in between A D and F G, but when extreme sensibility is required, additional resistances are inserted at these points. The wires are so arranged that either of them alone or two or three in series can be used.

If the plug is inserted between A B, No. 1 wire only is in circuit. If B C are plugged, wires 1 and 3 are in use; while if the plug is not inserted at all, the current passes through all the wires. The only connection not at once apparent is a stout copper wire connecting C and H beneath the base.

The same remarks as to construction apply equally to this instrument and the simpler form previously described. The base, however, would look better if made of stouter material. A bolder moulding should be run round the edges, and larger terminals used.

The value of the instrument would be much increased by the addition of a lid, which might have a glass top let in, if desired, and which would keep it in a much cleaner state than would be possible without, besides making it more convenient for transit.

The batteries are inserted between D and F, and the galvanometer between E and the sliding key.

If it is desired to obviate the necessity for loose wires over the instrument, all connections may be made underneath, and carried to terminals placed at convenient points on the ends of the base.

I have not attempted to go into the theory of the Wheatstone Bridge, but would refer any reader who wishes for information on the subject to Slingo & Brooker's "Electrical Engineering," or Ayrton's "Practical Electricity," in both of which the subject is well treated. It is also considered in the "Electrician" Primers, a useful series of tracts which have been recently noticed in "Our Guide to Good Things."

## DRAWER BEARERS, AND HOW TO FIT THEM.

BY DAVID DENNING.

Definition of Bearers—Object of Bearers—Nailing — Dowelling — Tenoning — Dovetailing.

It is very probable that many readers who know perfectly well what drawer bearers are may not recognise them by name, and of course, in such circumstances, to say anything about the way of fitting and fixing them would be comparatively useless. Without pretending to give any mathematically exact definition, it may suffice to say that the present paper has to do with the rails which are fixed between drawers in front, not with those which extend from back to front. If there is only one drawer, with, say, a cupboard under, the front rail separating the two is the drawer bearer, so that in a chest of, say, three long and two short drawers, there are three bearers; for though the bottom may in reality serve the purpose of one, we have nothing to do with it, as it is probably a solid board, or may be so, from back to front. The bearer then, so far as it concerns the object of the present paper, is merely the front one of three rails on which a drawer is supported, and does not refer to the solid boarding which is sometimes used instead.

It will readily be understood without insisting on the point that there are more ways than one by which the ends of these rails may be fastened into the carcase ends, and on a few of these I purpose offering a few remarks, which will no doubt serve to guide beginners in cabinet-making: or perhaps I should rather say those who have some mechanical skill, but are not so well acquainted with methods. From this it will be seen that a minute practical description of how to use the tools and do what is necessary is not in contemplation. I assume that the reader, theoretically at any rate, is acquainted with mortising, dowelling, etc., and even if he is not, he will have no difficulty in understanding the present article.

The object of bearers is primarily to separate drawers or to afford support to them, and secondly, to form a connection between the ends of the carcase, or outer casing, which they tend to hold together and render more rigid than they otherwise might be. It follows that the way they are fastened in is a matter worthy of consideration, and a few suggestions on the methods most commonly adopted it is hoped will enlarge the views of those who may have been in the habit of practising one or more, without thinking about anything more than the mechanical features of their work. It is assumed that everyone knows that the ends of a piece of cabinet work should be parallel with each other, and that the bearers should extend "square" across, or, to express it otherwise, the front opening between two ends and bearers ought to be strictly rectangular; for to those who think that the work may be done "anyhow" I have nothing to say, except that their ideas are not valuable, and that the sooner they alter them the better, if they wish to turn out good work. My remarks are addressed solely to careful workers who wish to excel.

Naturally, the simplest way of fastening the bearers in is by merely nailing them through the ends, but such a very primitive mode of working is seldom advisable, and would not be allowable in any but cheap common work. It may therefore be dismissed without further comment.

Then there is the better plan of tenoning the bearers, or the closely allied one of dowelling. Both of these are good methods, and are practised by equally competent cabinet-makers, some preferring one and some the other. Without expressing any personal opinion as to their respective merits, it will be sufficient to describe the chief characteristics, leaving readers to adopt their own course.

It is claimed for the mortise and tenon joint that it is stronger than the other, though for all practical purposes there is little difference in this respect. The tenon, or tenons—for perhaps two at each end of the bearer is the usual number—are left of the thickness of the wood, so that there is not the same risk of getting the bearers fixed other than straightly, as when dowelling is resorted to. When dowels are used, the holes, unless bored perpendicularly, will throw the bearers out of the straight line. Of course, when a really competent man is concerned, the assumption that he would make the holes in an improper way is rather a far-fetched one; but then, all workers are not proficients. With dowels it is often stated that there is greater speed and neatness of appearance, for the ends of the bearers need only be sawn square across for them to fit closely; on the other hand, those who prefer mortise and tenon do not allow that there is much difference in point of time, and that when properly done the joint is just as neat as the other. Beyond close fitting and glue, there is nothing in either of these joints to bind or clamp the ends together. The construction does not do so, for were it not for the top and bottom the ends could be pulled apart. In ordinary circumstances it is not necessary that the bearers should do more than they will if either dowelled or tenoned, but as a matter of theoretical good joinery, many may prefer that the bearers should bind the ends together, and occasionally it is an advantage to the work that they should do so. Of course, if we accept the dictum that good joinery consists in making the construction as firm as possible without using either nails or glue, it is almost necessary to adopt some other joint. Or if this is putting the matter too strongly, another form would be preferable, especially if absolute rigidity is required, rendering it practically impossible to pull the ends apart without destroying the bearers.

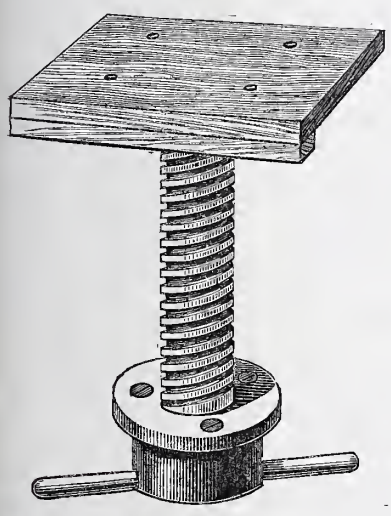
In such a joint the ends of the bearers are dovetailed, usually on the lower side only, and of course fit into corresponding sockets in the ends. In order to prevent the dovetails showing in front, they are cut back a short distance, say to the thickness of the facing slips which are so commonly employed, the sockets being stopped to an equal distance; the bearers are then driven in from the back. When the ends are thickened up in front, there is, of course, no possibility of a difficulty arising in doing this, as the sockets will only be in the thickening pieces, so that the dovetails can just be pushed into them. If the ends are of one thickness throughout, however, the case is somewhat different, as the groove must extend right to the back. When this is necessary it need not be of dovetail shape throughout, but merely in front for a space equal to the width of the bearer. For the rest of the distance it may be a plain channel of the thickness of the bearer, and will serve very well for the drawer runners to lie in. Instead of such a long groove, a

short one just behind the socket may be made, and not shorter than the width of the bearer which is let into it, before the ends are fastened up, and then pushed forward. The dovetail bearers may also be inserted from the front, if the appearance of the joint is not objected to, though even then they may be concealed by fastening facing-slips on afterwards. All this considered, if a really theoretically perfect joint is wanted, there is nothing better than the dovetailed bearers, though in practice any of the other methods are equally serviceable in most cases. The reader, however, will have little difficulty in deciding which form suits his purpose best, and with this I must leave him.

## MEANS, MODES, AND METHODS.

### A Suggestion for a Carver's Screw.

I do not think it is widely known, but a simple expedient to hold work while carving may be made as follows:—Obtain a music-stool screw (cost from one shilling), and a piece of any wood suitable in size for the work to be done. "Let in" the oblong plate of the screw flush to the underside of the piece of wood selected, and bore the screw-holes through the piece of wood. Select screws that will go through and project about ¼ in. beyond the top surface of the wood, and you have a useful block to



**Suggestion for Cheap Screw for Wood Carvers.**

fix the wood under treatment. If needful, a ledge can be fixed under the piece of wood, which, being in contact with the edge of the bench, will prevent the whole affair from turning. A hole in the bench and a turned block to which to fix the nut complete a cheap and useful carver's screw.

Several pieces of wood may be provided, and, if large, instead of screwing as advised, the piece of wood can be permanently fixed on the plate of the screw, and the carving fixed by any number of screws required round the margin. B. A. B.

### A Clean Method of Brazing.

This is sometimes a great desideratum. How often has a nice piece of work been destroyed by having the fire smoky just at the time it should not be!

A friend put me up to a wrinkle which entirely did away with this possibility.

It was to heat the article by putting it into a hot gas retort from which the charge had just been withdrawn.

It may not be known to everyone that coal-gas is made by putting the coal into a large metal box, or retort, which is brought to a high temperature, and thus separates the gas from the coke of the coal. The retorts are emptied periodically, and this is the opportunity for the brazier.

Having cleaned the surfaces to be joined and tied them together with iron wire, plenty of ground borax and spelter are put on the joint, and the entire piece of work run into the hot retort. Almost immediately it gets red-hot the spelter runs, and the job is done. Of course, this plan is not available for everybody, but I have no difficulty in inducing the gas-man to let me use his retort for a few minutes. J. L. D.

### Clearing Chimneys of Jackdaws' Nests.

If any of the readers of Work have had my experience in trying to clear out the masses of sticks and other rubbish which jackdaws pile into chimneys when nest-building, I am sure they will be glad of a wrinkle.

Having climbed to the top of a chimney with much fear and trembling, I spent three hours sitting on one chimney-pot, while with a heavy iron bar, used after the manner of a battering-ram, I tried to drive down a nest through the flue of another. It was all in vain. The nest, which was the result of many years' industry, resisted all my efforts, and was quite as springy and resilient at the end of the three hours' battering as before. At length, in desperation, I poured about half a pint of paraffin oil down upon the nest, and dropped some burning paper on to it. There was a grand blaze, and in a very few minutes the chimney was clear and a roaring wood fire in the grate.

This plan would not do in a city, and, of course, would be cruel if birds were in the nest. J. L. D.

## MASONS' WORK.

BY MUNIO.

Staircases—Arches Used in Masonry: Semicircular, Segmental, Elliptic, Pointed, Ogee, Tudor, Foiled, and Oblique Arches—Niches—Chimney-Pieces—Measuring.

*Staircases.*—Stone staircases are formed in various ways. In some the flights are straight, and sometimes they are divided by landings or half-paces; but as there is not often sufficient space for straight flights, they are formed with return flights, with landings or winders at the turns. The straight steps are termed fliers, and those which are narrower at one end than the other are termed winders. In turrets the steps are all winders, with a solid newel worked on the end, or they are fixed in a central newel of masonry.

The steps are sometimes supported in walls, and sometimes one end of the steps is fixed in the wall, and the other end supported by the step immediately under it. These are termed geometrical staircases.

In order to find the form of the steps for a geometrical staircase with winders, a plan must be made as shown in Fig. 43, from which the form of the steps may be obtained.

The steps are sometimes made plain, and sometimes moulded on the edge and the moulding returned across the end, as shown in Fig. 44. The rebated joint of the steps is squared from the slope underneath, and the steps should not be less than 2 in. thick at the thinnest side. The rise of the steps should be proportioned to the width, a wider step having a less rise than a narrower one. A step 12 in. wide should have a rise of 5½ in., and a step 10 in. wide a rise of 6½ in. To find the rise, divide the full height in inches by the number of steps. To find the bevel for working the underside of the steps, an elevation of each flight must be drawn, and also each set of winders, from which the bevels can be taken.

As the stairs are not usually fixed till the building is up, it is customary to form the grooves for the ends of the steps and landings by inserting bricks in the wall without mortar, and covering them with large flat stones; the bricks are drawn after the walls are up, leaving the grooves ready formed. The steps should be inserted about 9 in. into the wall at the end, and wedged firmly in, and a dowel inserted in the rebated joint near the other end. The landing has a similar joint where it rests on the top step. The landing is generally in one stone, but when in more than one the joints should be joggle-jointed. Mortises are cut in the ends of the steps in which the iron balusters are fixed, and run in with cement or melted lead.

*Arches used in Masonry.*—The arches principally used in masonry are the semicircular, the segmental, the elliptic, the pointed, the ogee, the Tudor, the foiled, and the oblique arches. The lowest portion of the arch is termed the springing, the top portion the crown. The stones forming the arch are sometimes termed voussoirs; the underside of the arch stones is termed the intrados or soffit, and the top side the extrados; the centre arch stone at the top is termed the key. Arches are plain on the face, sometimes chamfered or moulded on one or both faces. Inside arches of windows, doors, etc., are generally splayed; the joints of arches are sometimes rusticated.

Arches are turned or built on wood centres, which must be of proportionate strength to support the weight of the arch stones till keyed.

In setting a range of arches the quoins should be set up first, so that the face of the arch may be kept straight by means of a line or rule, and in walling between arches, when a line cannot be stretched, each course should be bevelled. Relieving arches are formed in the wall over lintels, door- and window-heads, etc.; they should always be turned from the outer end of the lintel or head. They are generally hammer-dressed, except in ashlar-work, when they are chisel-dressed.

*The Semicircular Arch.*—This arch is drawn from the centre of the springing line; the depth of the arch stones is then marked, and a second circular line drawn, which gives the line of the extrados. The key-stone is then marked, and the remainder of the arc divided equally, and lines drawn from these points, radiating to the centre, give the arch stones. Sometimes the extrados are not made parallel to the intrados, but are squared to join the wall stones. Fig. 45 represents a semicircular arch, half the arch stones being of equal length, and the remaining half squared at the extrados.

The stilted arch is a semicircular arch, with the sides carried downward in a straight line below the springing till they meet the impost or cap.

The horse-shoe arch is also semicircular, with the arc carried below the springing to the cap, which narrows the span of the arch.

*The Segmental Arch.*—This arch is less than a semicircle, and is drawn from below the springing line. The centre is found by dropping two perpendiculars from the centres of straight lines drawn from the rise of the arch to the springing on each side; the point of intersection of these perpendiculars is the centre from which the arch is drawn. The key is marked, and the arch divided in the same manner as the semicircular arch; the arch stones are sometimes squared at the extrados.

*The Elliptic Arch.*—This arch is half of an ellipse or oval, and is drawn from two centres on the springing line and one centre below the line; the key is marked off, and the arch stones found as previously described. The joints of each portion of the arch must be radiated to the centre from which it is drawn.

*The Pointed Arch.*—Pointed arches are of three kinds: the lancet, the equilateral, and the obtuse. The lancet is formed of two segments of a circle, the centres of which have a radius longer than the width of the arch.

The equilateral arch is formed of two segments of a circle, the radius of which is equal to the width of the arch.

The obtuse arch is formed of two segments of a circle, the radius of which is shorter than the width of the arch.

These arches are generally formed without a key, although in some cases a key is used. When the extrados are not made parallel to the intrados, they are cut as shown in Fig. 7 (page 97).

*The Ogee Arch.*—This arch is formed of four segments of a circle, the centres of two of which are on the springing line inside the arch, the other two being on the outside and level with the point of the arch, each side being formed of a double curve, convex below and concave above. It is generally used as a hood or label mould over another arch.

*The Tudor Arch.*—This arch is described from four centres, two level with the springing line and within the arch, and two below the springing. The arch stones are drawn in the same manner as the elliptic arch. For ordinary door- and window-heads it is often made in one stone, with a square hood moulding over it.

*Foiled Arches.*—These are of three kinds: the round-headed trefoil, the pointed trefoil, and the square-headed trefoil.

The round-headed trefoil is drawn from two centres on the springing line and one centre above. It is used chiefly as a heading for niches and blank arcades.

The pointed trefoil is drawn from two centres on the springing line and two above the springing. It is generally used for foliations in tracery work, within a pointed arch.

The square-headed trefoil (Fig. 46) is used for door- and window-heads. It is sometimes in one stone and sometimes in three, as shown.

*Oblique Arch.*—The oblique or skew arch is that form of arch in which the line of the abutments is not at right angles to the face of the arch. Oblique arches are of two kinds—one with plane joints and the other with spiral joints.

An oblique arch with plane joints is that in which the beds of the stones are in planes passing through the axis of the cylinder, the face being bevelled.

An oblique arch with spiral joints is that in which both the beds and joints form spiral surfaces. The arch stones are set square from the face, and consequently meet the springers at an angle; the springers are therefore made wider at one end than the other, the difference being generally equal to the width of the arch stones. They are used for the arches of bridges, and are generally segmental or elliptic in form.

*Niches.* — Niches are arched recesses formed in walls for statuary or ornamental purposes. They are generally semi-circular or semi-elliptical in plan, although other forms are used; the arched covering is of a semi-spherical form. When the openings are small, the arch is formed with one or two stones; but when the opening is large, the arch is formed in a similar manner to the semicircular arch, except that the arch stones diminish from the front to a point in the centre at the back of the recess, and the soffit is circular. In order to obviate cutting the arch stones to a point, a semicircular boss is placed in the centre of the recess, the face of which is worked to the curve of the soffit, and the bed is radiated. Upon this the narrow ends of the arch stones rest.

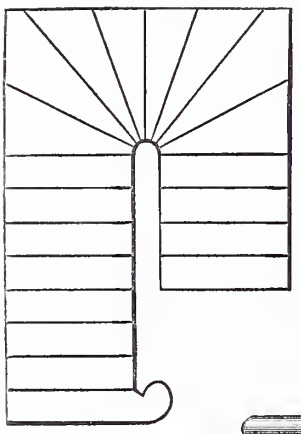


Fig. 43.—Plan of Staircase.

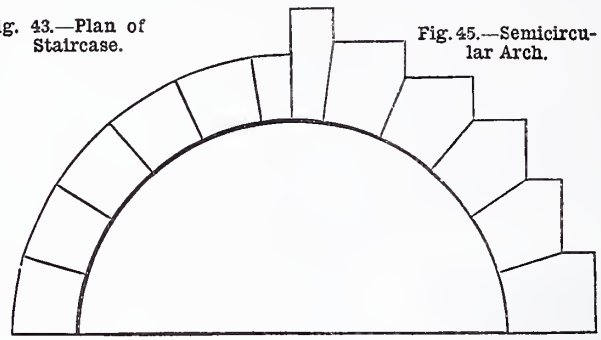

Fig. 45.—Semicircular Arch.

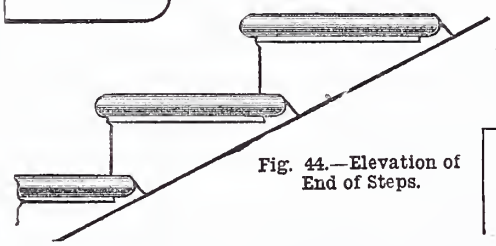

Fig. 44.—Elevation of End of Steps.

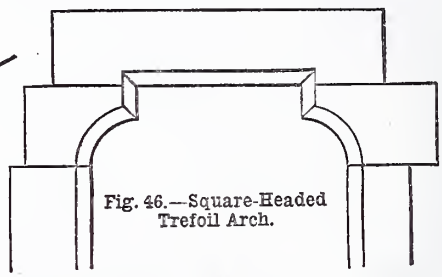

Fig. 46.—Square-Headed Trefoil Arch.

*Chimney-Pieces.* — Chimney-pieces are sometimes formed with solid jambs and mantels, from 6 in. wide and upwards. They are fixed in arched recesses left in the chimney breast, and the shelf is pinned into the wall; they are worked plain, chamfered, or moulded. Sometimes the jambs and mantel are formed of sawn slabs, from 1 in. thick. They are fixed by means of copper or brass cramps let into mortises cut in each stone; the shelves are pinned into the walls, and the angles are sometimes chamfered or moulded.

*Measuring.*—Masons' work is measured by the lineal foot, the superficial foot or yard, and by the cubic foot or yard.

Footings are measured by the superficial foot, the thickness being given.

Foundation walls above 2 ft. in thickness are measured by the cubic yard. Ordinary rubble walls up to 2 ft. in thickness are measured by the superficial yard, deducting the net size of openings.

Blocking course or hammer-dressed walling is measured by the superficial yard, deducting the openings, and giving the average width of the beds.

Ashlar-work is measured by the cubic foot for the stone, the face-dressing by the superficial foot, and the beds and joints by the superficial foot.

Reveals, splays, grooves, chases, throatings, chamfers, etc., are measured by the lineal foot.

Window-heads, sills, plinths, strings, and similar work under 9 in. thick, are measured by the lineal foot, measuring the girth for the dressing.

Arches, cornices, copings, parapets, etc., are measured by the cubic foot for the stone, and the dressing by the superficial foot. Moulded work is girthed by the tape measure, pressing it into all the members of the moulding.

Arches are girthed at the intrados and the extrados, and the two girths added together and divided by two for a mean girth.

To find the stone in an arch, multiply the mean girth by the depth of the arch stones, and this product by the length for the contents.

Paving and flagging are measured by the superficial yard, specifying the quality and thickness.

Kerb and channel are measured by the lineal foot.

Returned mouldings are measured round the ends, and the number of mitres given as either external or internal mitres.

Steps and thresholds are measured by the lineal foot, and girthed for the dressing.

Quoins are measured by the cubic foot for the stone, and the dressing by the superficial foot. Sometimes they are measured by the lineal foot in height, the size being given.

The practice of measuring varies in different districts; but it is trusted, from what has been given, that readers will understand the basis on which it is calculated.

## DESIGNS FOR FINGER PLATES OR PANELS IN REPOUSSÉ WORK.

BY ROBERT COXON.

THESE two designs are drawn especially to assist the brass worker in producing good work in repoussé, without demanding too much labour; and when carefully traced and worked out, will be found to produce charming panels, either for the purpose of door plates, or other panel work for furniture or wall decoration.

By first carefully tracing the drawing, by means of the ordinary carbonised paper, between the brass and the drawing—using a hard lead pencil or ivory tracer—you will

TWO DESIGNS FOR FINGER PLATES OR PANELS IN REPOUSSÉ WORK.

get a good line on the brass to commence with; and having secured it by screws to a stout piece of wood, about 12 in. by 6 in. and 1 in. thick, upon which previously place a stout piece of sheet-lead between the brass and wood board, commence by marking all straight lines first with the straight tracer, and the curved ones with their respective tools. Having done which, work out, with the blunt or rounded edged tools, the leaf, scroll, and beads, using as much care as possible in modelling these, as a great part of the effect depends upon this part of the work, and finish by working up the background to leaf work and centre scrolls with their respective tools.

This work may seem, upon the effect turned out, to be extremely difficult, but, on the contrary, it is very simple, many ladies and children having produced good results from patient work; and to those who have not tried it before, it can be recommended as something novel, and producing surprisingly effective results.

## OUR GUIDE TO GOOD THINGS.

*** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

58.—Montgomerie's Scaffold Chain.

Everybody who has paid any attention to workmen when engaged in the work of putting up a scaffold must have noticed the way in which the horizontal spars or ledgers are bound to the vertical poles by means of ropes, which are tightened by driving in wooden wedges between the timbers themselves or between the rope and the timbers which it holds together, in order to bring the tension of the rope and its binding force on the poles to a maximum. The use of ropes for work of this kind is now rendered unnecessary for all who are ready and willing to adopt other means, by the introduction of Montgomerie's Scaffold Chain, which has been submitted for notice, and is supplied by Mr. Edward Preston, tool and cutlery warehouse, 8, Snow Hill, Birmingham. The illustration of the chain given in Fig. 1 represents the position assumed by the chain when holding ledgers, but, as it has doubtless occurred to the reader, other connections, different to this, may be made in an equally satisfactory manner. Fig. 2 shows the manner in which the chain is used. First screw the nut, C, away from the hook end, A, until it is stopped by the flat head at the end of the screw. Then let the barrel, B, with chain attached, slip down to the nut; place the chain in the position desired, and insert the hook in the link which happens to be most convenient, leaving any links beyond the one into which the hook is placed hanging loose, after which screw the nut, C, towards the hook, A, until the necessary tightness is attained. Even if the nut be not screwed up tight, the chain will not slip down, as the ledger causes sufficient strain on it, or "drag," as it is technically called, to make it hold. The chain, as is very truly asserted, has great advantages, and entirely supersedes ropes, as well as chains or short pieces of chain with a spike at each end, and enables the builder entirely to dispense with wedges for tightening ropes, which is properly regarded as one of the chief disadvantages of the present system of scaffold building; the wear and tear of the ropes, owing to the great strain put on them by the wedges, being another, and one which points to the economy effected by the use of the chain, which is rendered still more palpable by the fact that when the screw gets worn, as it will do, by frequent use, it can be renewed at small cost. Further, the strength of the chain and its durability, when compared with the rope, and the fact that the action of the screw tends to make the grip of the chain on the poles far more tight and rigid than that of the rope even when wedged up to the uttermost, clearly indicate that by its adoption scaffold accidents through collapse of the structure will be reduced to a minimum. The chains are supplied in three sizes—namely, 30 in. long with links $\frac{1}{2}$ in. thick, tested to 5 cwt., at 24s. per dozen; 36 in. with links $\frac{5}{16}$ in. thick, tested to 12 cwt., at 28s. per dozen; and 36 in. long with links $\frac{3}{8}$ in. thick, tested to 22 cwt., at 33s. per dozen. Preston's Improved Wrench Hammer, shown in Fig. 3, and combining in itself two separate tools—namely, a wrench and a hammer—sold at 5s. 6d., will be found to possess special utility for tightening up the nut; and Mr. Preston also supplies for 1s. good spanners, taking 1 in. nuts at one end and $\frac{5}{8}$ in. nuts at the other.

Another advantage presented by the use of Montgomerie's Scaffold Chain, and one which has not yet been noticed, is the saving of time effected in putting up and taking down these temporary structures, for it will be seen at once that it will take far more time to adjust, secure, and wedge up a piece of rope than it will to put the hook into the most convenient link of the chain and screw up the nut. The Editor.

## SUGGESTIONS FOR WORKERS AND HINTS TO INVENTORS.

Envelopes. — Everybody knows the inconvenience of trying to introduce into an envelope just a little more matter than it will hold, while the domestic stationery case seldom contains any sizes larger than those used in every-day correspondence. There is room for a design which will suit either the ordinary note or the larger package of enclosures it is occasionally desirable to enclose. Such an envelope could not, of course, be gummed down to a fixed size; while it must look neat, no matter its spread. Such a device seems simple enough at first sight, but in reality requires some ingenuity to produce—the problem, however, being well within the range of ordinary ingenuity. As such an envelope is wanted by the stationery trade, a successful design would, in all probability, prove very remunerative.

Bicycle Tyres. — Despite the numerous patterns, pneumatic, etc., now on the market, manufacturers of cycles are asking for something which combines all the advantages of the pneumatic without its liability to be pricked so as to render it virtually useless. The solution will probably be found to be in some combination of metal and rubber, so as to render the latter independent of mere air support. All cyclists are agreed that, no matter how apparently excellent the patterns now in use, finality has by no means been reached. Whether existing lines should be followed, or a new and bold departure take their place, is a question just now exercising many ingenious minds. Meanwhile, our readers may be glad to have their attention directed to the matter.

Cycle Boots.—Apropos of cycling matters, we note that votaries of the wheel are asking for a boot or gaiter which, while not proclaiming its object so as to mark the wearer as a cyclist when walking about, shall, nevertheless, save the trouser-ends from dirt or injury. Bootmakers are (rightly) regarded as the most conservative of artisans, but, in view of the real want expressed, a suitable pattern would doubtless find a manufacturer.

Pencil and Paper.—A large number of people grumble, not mercly at having to sharpen the familiar lead pencil, but even at the slight trouble involved in keeping a pencil-case lead properly protruding and sufficiently sharp. Why should not such people be suited by the invention of an almost lasting *stylus* which would at once produce a well-defined mark upon prepared paper? The old-fashioned pocket-books, with their (literally) leaden writing instruments, were a step in this direction, but they were never liked. People like to see what they have written standing out in bold black characters; and an invention of this nature would probably take.

Smokeless Briquettes.—Every now and then the invention of an absolutely smokeless briquette (which, as most people know, is an artificial compound of coal-dust, pitch, etc.) is announced by some sanguine inventor, who invariably finds that, under some unforeseen conditions, his compound is a failure. There is a large field for inventive effort in this direction, and the lucky discoverer of a really smokeless fuel will excite the envy and admiration of his friends. It need scarcely be said that an open space for experiments is a *sine quâ non* to those who would essay an endeavour to discover the much-needed substitute for smoky coal.

Anti-Scale Preparations.—Despite numerous attempts to find a really satisfactory preparation that will prevent scaling in boilers, the field is still open to anybody who can discover the much-wanted substance. Eucalyptus oil, kerosene, vinegar, the sawdust of certain woods, and an infinity of other materials, have been tried, pronounced successful, and—failed under crucial tests. Very probably this has arisen because water derived from one source requires different treatment from that derived from another. The fact undoubtedly remains that while power users in some localities declare that So-and-so's mixture is perfectly successful, people at other places find it quite useless.

## SHOP:

### A Corner for Those who Want to Talk It.

**** *In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—Letters from Correspondents.

**Rate of Circular Saws.**—B. A. B. (*Hampstead*) writes:—"May I say that I agree with CHOPSTICK (see WORK, No. 120, page 251), especially when he claims that for cutting thin stuff, grooving, rebating, etc., the advantages of a small circular saw are great. The great thing is to abolish 'slip.' Now, both the Britannia Co. and Barnes, of the United States of America, make circular saw benches which do away with slip, and I have no hesitation in saying that for small work, such as beehives and fittings, cameras and dark slides, book slides, and for preparing small things for turning, a hand- or foot-power circular saw, used with care and judgment, is a great advautage."

**Rate of Circular Saws.**—A. R. (*Scorrier Saw Mills*) writes:—"With pleasure I reply to CHOPSTICK (see WORK, No. 120, page 251). The letter he refers to in No. 116, page 187, emanated from me, and not from A WOODWORKER. CHOPSTICK asks if I could get a joiner to cut 3 in. deep with a hand rip saw, insinuating that it is almost impossible to find a man to cut 3 in. deep with a rip saw. This is absurd. Within a radius of a very few miles, I could, if needed, get not only one, but scores of joiners who would rip 3 in. deep in red or yellow pine, and even deeper than that. In fact, I have seen work done with a hand rip saw which it would be impossible to do with a circular saw driven by hand. I am acquainted with several workmen who have small circular saw-benches within two miles of my residence, and the men employed at each place inform me that they prefer ripping stuff from 2 in. to 3 in. deep with the hand rip saw to turning a wheel to drive a circular saw, which they term hard labour. CHOPSTICK may have a man who prefers turning the wheel for the simple reason that he is not a skilled mechanic. I am of opinion that nine out of ten mechanics would not accept such a job. All with whom I am aequainted prefer the hand rip saw for such work. Again, if you have a labourer to turn the wheel, a tradesman has to do the sawing, and, taking all things into consideration, I maintain that the haud rip saw in such work has the advantage. I agree with CHOPSTICK that where there is a deal of rabbeting and grooving to be done, the circular saw bench is very useful in grooving ⅜ in. and ½ in. deep. Not long since I ordered a ¼ in. grooving saw, and put it in working order for a friend who had a quantity of grooving to do, and the work was despatched in much less time than if it had been done with the plough-iron. But at the same place they preferred ripping above 2 in. deep with the hand rip saw. Again, not long ago a joiner came to me and said he had a deal of ripping to do in 2½ in. and 3 in. red pine, but his saw was cutting hollow and round. I looked at the saw, and found it was slightly bent. I sharpened and straightened it for him, and met him a day or two after, when he said (using his own words) 'he had been ripping two days with it, and it went *grand*.' Again, I pass a shop daily where there is a small circular saw bench, and if you were to go into the shop you could not see the bench, because it is buried with waste timber; and if they have not time to bring the timber to our works to be sawn, they rip it with the hand saw. A circular saw by hand in certain work is not work for a man; but I think the above will fully confirm my argument on page 187, Vol. III., of WORK."

**Varnish.**—H. L. (*Urmston*) writes:—"Referring to your reply regarding varnish to J. T. (*Nottingham*), in your issue No. 121, page 268, I have used a cold lacquer made by the Dalton Manufacturing Company, whose offices are at 12, Peter Street, Manchester, which I have found excellent for all kinds of metal. It dries quickly and becomes perfectly hard, and entirely free from the stickiness mentioned in your reply. It requires no heat or other preparation, and can be used by anyone. They make it pure crystal, also black, and in a great number of shades, all of which are transparent. It can be bought in shilling bottles, also in large quantities."

**Gilding on Glass.**—T. W. V. (*Leicester*) writes:—"Having seen both H. L. B.'s and BLINKER'S answer to YOUNG SIGNWRITER (see WORK, No. 121), with all respect to your correspondents, I may say that their description of gilding on glass is not the practical method. Having at times seen hints in WORK that have been very useful to me, I would like to give YOUNG SIGNWRITER, or any other aspirant in glass gilding, the practical way of doing it. This work is usually done on shop windows. Mark the design on the outside with wax, then go inside and clean the window. When this is done, size in the letters (size with spirits of wine is best—see H. L. B.'s instructions in WORK, No. 112). There is no need to be particular in the cutting in with size, but it is advisable to have as little size as possible in front of the leaf. Only size a letter or two at once. When the gilding is completed and dry, see to all pin holes. Then with japan black line the letters in (you will be able to see the wax line through the gold leaf). It is best to size the gold before blacking, but it is not necessary to do so. When all the letters are written, let the black dry; this will take only a few minutes. Clean out your brushes while this dries. Then, with a little warm water and sponge, wash all over the letters and window, and the gold outside your letters and size will come off. I will give a further bit of valuable information to the glass writer. Get some clear varnish and line ⅛ in. outside the letters, which will protect them from water. If you should prefer a stencil (which is very useful for facias), cut the letters out of paper, and stencil the black on gold leaf instead of writing with a brush."

### II.—Questions Answered by Editor and Staff.

**Monogram for Illuminating.**—A. C. (*Leicester*).—The following monogram, E. E., is in answer to the request of A. C. (*Leicester*). This correspondent omitted to mention the object for which his design was intended. This should always be

E E Monogram Design.

stated, as monograms for different purposes require different treatment. For instance, one drawn for fretwork, if used for illuminating, would present a very wooden and clumsy appearance, and *vice versâ* the result will be equally inartistic, therefore unsatisfactory.—A. C.

**Hall-Marking.**—J. H. W. (*Homerton*).—I fear that it is not possible to re-hall-mark your ring, but you can judge for yourself from what follows, and if you decide, after all, to have it done, the Editor will, on receipt of a note from you, endeavour to give you the name of a manufacturing jeweller who would do the job—that is, always providing that you do not know of anybody yourself in the line. First, then, you should know that it is necessary to obtain at least 12 grains of the gold from the ring itself, for the purpose of obtaining by assay the proportion of fine gold that there is in the article. That matter, however, is carried out at the Gold smiths' Hall; but you could not take it there yourself, for no work is received unless by firms that have already registered their name-punch. The hall-mark, being a trustworthy guarantee, is not placed on any work without a thorough test. So to prevent any cheating, the ring has to be cut open to show that the quality is the same all through, and it is partly laid flat to allow of the marks being struck. The authorities at the "Hall" have the right of scraping or filing or cutting the quantity of gold required from any part they choose of the work sent in. Now, in this case, where the ring has been in bad hands, it is very doubtful if it would once more pass the Hall; for even if the new piece put in is fully 15-carat, there will probably be more solder about it than there should be, and so the general quality will be lowered. The Assay Department of the Goldsmiths' Hall has the power of smashing any work that does not come up to the stated quality, although now I do not think they do so in all cases, but return it unmarked to the sender. I said that I would try and find somebody to do this job for you, but it is a very unthankful business; for no manufacturer likes to have his work sent back through being of inferior quality, nor will they run any risk of it, as a rule. It is almost a pity that you did not get skilled advice on this business, for then the dishonest jeweller who tried to pass off a piece of base metal in place of your gold could have been made to pay for his trickery; and I should be quite willing to have helped you to make him smart for damaging your ring and attempting to rob you of a portion of its gold. Thus, you see, to re-hall-mark the ring is an unsatisfactory job to take up; and even if successful it would cost from 5s. upwards before the ring is again in fit condition to wear. The hall-marking of a portion is distinctly forbidden. If you desire to know if it is 15-carat gold that has been put in, nearly any jeweller ought to be able to tell you that; but if you desire an authoritative opinion, you can obtain it from Messrs. Johnson, Matthey & Co., Assay Office, Hatton Garden, by sending 1s. 6d. and cost of return postage, with a request for them to make a "parting" assay of the back part of the ring. It will, as I have already said, damage it somewhat, for the half-pennyweight requires some scraping to obtain, and it would be simpler to cut a piece right out, which they very likely would do.—H. S. G.

**Reflecting Telescope and Eye-piece Lenses.**—E. G. S. W. (*Weybridge*).—I am glad to learn that your speculum defines well. Of course, you know that by using it without a flat you simply form an Herschelian telescope. In selecting the plate-glass for the experimental "flat," try and get a piece of an old good mirror—more care is likely to have been taken in the original polishing of such glass. The scratches on the eye-piece lens should not matter much for preliminary tests; and I fear the price asked by Wood, of Cheapside, is the price any optician will ask. I wrote on your behalf to Messrs. Lancaster & Son, of Birmingham, and their catalogue is likely to be of use to you or any other amateur. They express their readiness to supply any kind of lenses that may be required. The price they name for lenses for eye-pieces is—for low powers 3s. each set, and for high powers 4s. each set. The latter price, you will see, is the same as that asked by Messrs. Wood. Perhaps some reader in actual touch with the trade will come to our assistance, and tell us if reliable lenses for astronomical eye-piece work, edged and centred, can be obtained anywhere at a cheaper price than that given above. The firm I previously referred you to has, as you say, ceased to exist. I should strongly advise you to make an effort to buy from an old-established maker one complete eye-piece of medium power (say, 150 equivalent). This should cost you from 10s. to 12s. 6d., and, possessing it, you could be quite sure that any observed error must be in the speculum. This, as you will by this time know, means more than it sounds.—E. A. F.

**Upholstery.**—F. W. R. (*Harling*).—I am afraid it is useless to give you names of firms dealing in the class of articles you want, for if you cannot see them in the pages of the periodical you mention, I am almost sure you would overlook them in WORK. I do not think there is anything commonly used in the upholstery trade which is not advertised by some firm or other, and to make a selection between the merits of competing houses is not our province. Of course, you cannot expect each advertiser to give a complete list of all the articles they deal in, but you can surely use your own judgment, even if you have no personal knowledge of the trade. Thus, if you see a man advertising general hardware for cabinet-makers, etc., surely it will occur to you that he would be a likely one to apply to for tacks, gimp-pins, studs, etc., even though he does not say in his advertisement that he supplies these. To give you a complete list of everything used would take up more space than can be spared; but if you cannot avail yourself of the above hints, let us know, and state exactly what you want, and you will be helped. At present, even among those things you name, you are too indefinite. For example, you mention "stuffing materials." Do you mean hair, flock, wool, alva, fibre or other stuffing, or all of them? Then, do you want blind materials, bedding, and so on? Really, if inquirers knew how much more definitely they could be answered, they would not hesitate to be more explicit than they are. If it is worth while for the publishers to place at their disposal several columns of "Shop," and for members of the staff to devote their time and experience to answering questions on any branch of practical work, it ought not to be too much trouble for inquirers to tell us what they want to know. Too many, like yourself apparently, seem to think that the vaguest hints as to their difficulties and wants are sufficient to enable us to help them. If you and other readers will kindly note these remarks, and act on them, you may be sure that no trouble is spared in endeavouring to assist; but if you cannot state your wants, it seems hardly fair that valuable space and time should be taken up in giving you the attention expected. Inquiries cannot be answered privately through the post.—D. D.

**Fretwork Patterns.**—D. B. J. (*Dalbeattie*).—I am sorry that I cannot agree with your complaint that fretwork patterns are too dear. You must remember that the publishers must pay for designs, labour, and incidental expenses, as well as make a reasonable profit. Good designs and work cost money. The one you forward as a specimen of cheap work may be satisfactory to some fret-cutters, but I cannot imagine anyone who knows anything of design, or who is able to do good work,

wasting time and material over it. This is far from saying that it is not worth the money charged for it, for the price being so low very little can be expected; but it is in no way better, or even such good value as many of the most expensive designs which are issued. You might as well complain of wood, glass, hinges, and the other items you name being too costly to allow of your making a profit on your work as of designs. Of course, you are aware that when making up fretwork articles, especially if for sale, it is not economical to use a printed pattern for each, but is better to take a heelball rubbing, or adopt one or other of the well-known processes for reproducing designs. You want to know where you can get patterns for less than 2s. 6d. each; but as you have several catalogues, I am afraid you have not looked through them, for I do not know of any—and I am acquainted with all the chief ones—which has not several under this figure. However, to give you names, I may mention those of Harger, Settle; Skinner, East Dereham; Zilles, London; Busschotts, Liverpool. The latter two supply principally German and Italian designs respectively at low prices.—D. A.

**Camera.**—A. W. (*Paisley*) forgets that his very abbreviated descriptions are somewhat difficult to follow. He can scarcely expect any criticism on anything that is not actually explained, and that such and such things *may* be made in other ways than described, in order to meet objections, is altogether outside the question. Has A. W. actually made a working instrument according to his diagrams? If not, we should advise him to do so; for a thing may seem all right on paper, but in reality be very different. With regard to his box to be used as a dark tent, it seems to us inconvenient and unnecessary in these days of dry plates, when development is seldom or never done out-of-doors, and indoors a larger working room is desirable. With the wet collodion process, something of the kind was essential, and Edwards brought out his Graphogenic apparatus to meet the want where the development was conducted in a ruby glass box. Practically it was a failure, although no trouble was spared in the manufacture, and every supposed requirement was met. We can only reiterate that A. W. had better make the apparatus and try it, or let some *practised photographer* do so, in order to estimate its working value correctly.—D.

**Leclanchè Battery.**—D. A. R. (*Stockton*).—Your "electric battery" is known by the name of the Leclanchè battery. In answer to your questions—(1) The outer jars are charged with a mixture of sal-ammoniac and water. Sal-ammoniac dissolved in water until the water will dissolve no more. This is named a saturated solution. Dilute this with one-third more water to form the battery solution, and fill the cells to within one inch of their tops. (2) This charge may not need renewal for three years, or it may only last three weeks if the bells are rung continuously, or the circuit leaks. (3) You may compare the battery to a cistern of water if you choose to do so. You will then understand that you can get no more out of it than you put in the cells; but do not imagine that the electricity runs out as a liquid, and therefore empties the battery jars of the liquid with which they were charged. The liquid sinks in the jars because the water of the solution is evaporated and passes into the air. This takes place more rapidly in warm weather and in warm situations than in cold, hence the battery should be kept in a cool place. One jar may be warmer than the other, and this may cause "the water to disappear from it in much less time than the other." There is much less surface of zinc exposed to the solution when the jars are only half full, consequently there is more resistance in the battery, and less current available for the bells. As the battery does not furnish enough current to ring the bells, they stop ringing. Always keep the solution up to its first water line by adding a little rain water occasionally. (4) The "jars may be worked out" with a year's use if this has been excessive or the circuit has leaked. A Leclanchè battery is "worked out" when the peroxide of manganese in the porous cells has given up all its free oxygen and passed into the form of a sesquioxide. Take out the porous cells and soak them in warm water for two or three hours. Clean the zinc rods and the outer cells, then charge the battery with a fresh sal-ammoniac solution. If the battery works all right after this, the porous cells are not worked out. (5) Two small jars ("1s. 3d. size") are barely enough to ring even two small bells.—G. E. B.

**Black Stain.** — LITTLE JIM. — What kind of bracket is it? If it is of wood, then why wish to make it like black marble or enamelled-slate time-pieces? To use this effect successfully, your bracket must be devoid of ornamentation. In any case, if you wish a very *lustrous* black, use black enamel upon a coating of flat black paint. A less brilliant surface would probably look the best, for which ebonise and then French polish. Refer to Index, Vol. II.—F. P.

**Aquarium Fountain.**—J. P. (*Edinburgh*).—An illustrated article upon the above will appear in WORK in due course, but, pending its appearance, if you are in a hurry, you might with advantage study the description of a Self-acting Fountain in No. 69 of WORK. If you look at the diagram illustrating the working of the fountain, you will see that *the depth of the basin* would be the only material alteration required to make that particular design answer for an aquarium—the jet-pipe and filling-plug, of course, being raised to the necessary height. As to any fountain being "self-feeding," that is simply an idle wish. The only advantage in trying to make one that I know of is the certainty that the worker would leave the job much wiser than he started.—C. M. W.

**Bell-Ringer's Table.**—RINGER.—I give a sketch of a simple portable table which I have designed to fold up into the space required, viz., 3 ft. long and 1 ft. 8 in. wide, to be used as a handbell-ringer's table. It is composed of eleven pieces when complete, as the following:—Four pieces hinged in centre to form top, size when folded 2 ft. 9 in. by 1 ft. 6 in. (see Fig. 5); these pieces should be properly framed-clamped to make them flush on both sides; they will also be lighter made this way than if they were clamped with battens, for you can hardly have the top out of less than 1 in. stuff. Two pieces hinged in three places to form long rails out of 3 in. by 1 in., as in Fig. 4; these are secured to the uprights with thumb-screws. Two pieces hinged in five places to form struts or stiffening pieces, secured to the long rails,

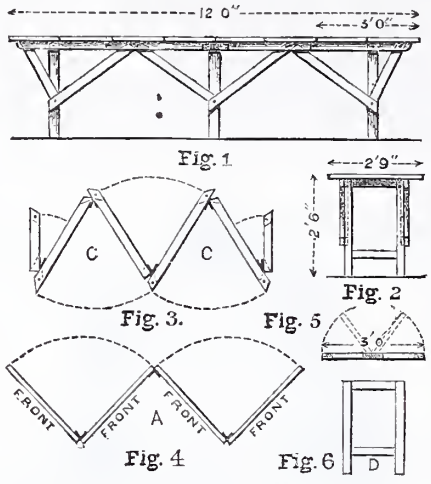

Fig. 1 Fig. 2 Fig. 3. Fig. 5 Fig. 4 Fig. 6

**Bell-Ringer's Table. Fig. 1.—Elevation of Table. Fig. 2.—End View. Fig. 3.—Struts, showing Method of Hingeing. Fig. 4.—Front and Back Rails, showing Method of Hingeing. Fig. 5.—Flaps. Fig. 6.—Framed Support.**

A, and the uprights, D, with thumb-screws (see Fig. 4); and three framed uprights, Fig. 6, with 2 in. legs and 2½ in. by 1 in. rails, making eleven pieces in all. The method of putting the table together is as follows:—First stand your uprights in position, open your two top rails, and connect the top rails to uprights with thumb-screws; next open your two stiffening pieces, which are halved behind the rails and in front of the uprights, and fix those in the same manner. These stiffening pieces should be 2 in. square, to allow of them being halved 1 in. behind rails and 1 in. in front of uprights. Now screw the four leaves directly on to the top of long rails and uprights with coarse wood screws; and, if properly made, I think you will find you have a perfectly rigid table, which I hope will suit you.—E. D.

**Pencil-Sharpener.**—J. M. (*Dorset*).—The knife-chisel pencil-sharpener which you forward is an ordinary knife cut in half crosswise, the piece remaining attached to the handle having the narrow edge caused by the severance sharpened in the manner in which a chisel is treated. I have given it an active trial for several days. I still prefer the method described on page 697, Vol. II., No. 95, of WORK. I have suggested one or two points as improvements. Your idea is certainly an excellent one for those entering a draughtsman's office, or for those who may not have become used to any other practice; and as you say you are an invalid, and wish to utilise the invention profitably, I should advise you to communicate with the different tool makers who advertise in WORK.

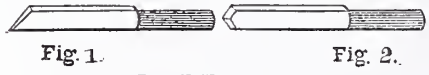

Fig. 1. Fig. 2.

Pencil-Sharpener.

The publication of this reply, of course, offers to all the opportunity of making a chisel-knife pencil-sharpener; but you must bear in mind that this will be the means of testing its usefulness, and, if found of service, this should be a very good reason for the wholesale manufacture of such an article, and the inducement of some firm to take the matter up. I will explain why I consider the adoption of my sketches as improvements on your sharpener, which has a chisel-edge at right angles to the long edge. First, I must say that the way to sharpen a pencil is to hold it firmly upon a board, and use the chisel-edge, cutting away from the operator. During these movements it is difficult to retain the edge parallel with the surface of the board, the consequence being that the right-hand corner of the knife digs occasionally into the board. With a chisel-edge as in Fig. 1 this is obviated.—J. S.

**Spindles.**—J. P. (*Woolwich*).—Like you, I have to send to the centres of the cabinet trade, and find Banks, wood turner, of 65, Holywell Lane, and Lyssow, of Old Street, suitable men for spindles and turnery goods. Lyssow sells bone knobs and carved panels, and a good assortment of other fittings. For ironmongery and brass work, H. Snuggs, 331, Old Street, E.C., is excellent—very large stock and moderate prices. While writing, I might tell J. P. that for veneers, stringing, marquetry ornaments, etc., McEwan, 282, Old Street, E.C., has been of great service to me when I have had repairs to do in ebony, ivory, etc.—B. A. B.

**Fretwork Patterns.**—H. R. (*Manchester*) desires a pattern showing a farmhouse. If any such is in the market, it is probable that he could be helped to it by applying to one of the large dealers in such things, such as Messrs. Zilles & Co., 21, Wilson Street, Finsbury, London, E.C.; Messrs. Harger Brothers, Settle, Yorkshire; or Mr. G. Busschotts, Park Lane, Liverpool.—M. M.

**Fine Lines in Fretwork.**—G. T. N. (*Finsbury Park*).—Mention was made in an early number of WORK of a *wire-thread fret saw*, introduced by Messrs. Richard Melhuish & Sons, 85 and 87, Fetter Lane, E.C. This is merely a steel wire jagged with saw teeth, and it would, I imagine, help G. T. N. out of his difficulties. One of his troubles is that the hole necessary to admit an ordinary saw spoils the effect, and this saw, of course, would require a relatively small hole—no larger, in fact, than the width of the cut. If Messrs. Melhuish are prepared (as they doubtless are by this time) to supply customers with wire saws of different sizes, they can probably supply suitable drills to use with them.—M. M.

**Damaged Dulcimer, etc.**—A PLAYER.—Please don't apologise for "any trouble you may give." The fact of such an experienced hand as yourself asking for advice is a striking proof that WORK is what it aims at being—viz., "a journal for *all* workmen, professional and amateur." You can certainly put a new soundboard in your dulcimer without pulling the instrument all to pieces, and to do so proceed thus:—Remove the damaged one by taking out the heading or moulding that runs all round; do this, if possible, without breaking it, as the same moulding will do again. Then bore a hole of about ¾ in. diameter at each corner close up to the blocks, but ¾ in. from the front and back; this will clear the braces. With a small saw you can now cut from one hole to another along the blocks, and also as far as the inner treble bridge at back and front. Here you had better stop, and commence again on the other side of the bridge, and so continue to the bass bridge. Having gone quite round, you will be able to remove the damaged board without trouble. Now remove the pieces that have been left on the tops of the braces, being very careful over this, or you will splinter the veneer from the tops of the facings. Then trim off the sides level with the blocks, leaving the grooves filled with the edges of the old board. You will not be able to fit the new board into these grooves, so you must get out two fillets ¾ in. by ½ in., and glue and brad one on each block, with its top edge exactly level with the *bottom* edge of the groove, and also with the top edge of the brace. You will now have a rebate all round, on which your new soundboard will rest. You say the old one is of cedar—I suppose you mean the scented or pencil cedar. By all means put in a new one of the same kind of wood if you can get it, but if not, put in one of pine. Having carefully fitted it, remove it and clean it up to the exact thickness of the old one; then cut the sound-holes and polish it. If of cedar, polish it in its natural colour; but if of pine, polish it black. It is now ready for fixing. To fix it, it need be only fastened with ¾ in. brads all round—brads about 2 in. apart. If you have been able to remove the moulding without breaking it, you can now replace it, and having put in the sound-hole rings, the instrument will be ready for re-stringing, after which it should be "as good as new." The second instrument about which you inquire, and of which you send a sketch, is a "bow or streich zither." It appears from your drawing to be a pretty good one. I presume the frets and stops are only approximate, as if they are copied exactly from the finger-board, it is incorrectly fretted. It should be strung as follows: 1st, No. 7 steel; 2nd, No. 8 steel; 3rd, No. 8 brass; 4th, steel overspun with copper. It is tuned the same as the violin. As its name implies, it is played with a bow, and should have on the underside three feet, with a small sharp spike in each, which serve to keep it steady on the table. As a rule, the tone is very poor and thin, and the instrument is being supplanted by the "viola zither" and "Philoméle."—R. F.

**Provisional Protection.** — PROTECTION. — If, under the circumstances named, B should attempt to obtain a patent, he can be opposed by C on the ground of his having obtained the invention from him. If, however, B has got a provisional protection granted to him before the date of A's application, and his title and provisional specification are wide enough to cover the plans of A, then it will be difficult for him to get redress. If it happens that A is before B, and completes his patent, B will be unable to use his improvements, except under a licence from A. It would be necessary, however, before either party proceeds against the other for an infringement, that he should possess the sealed

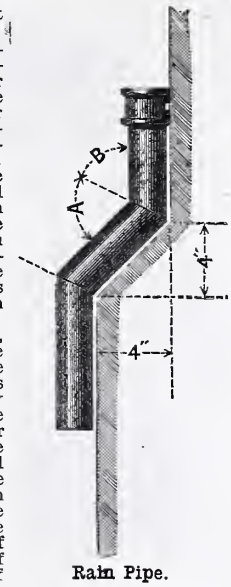
patent, as, until he has got it, he has no tangible rights to fight for, or to be infringed. Provisional protection merely assures him that no later applicant shall go before him in obtaining the right he seeks.—C. E.

**Invention.** — PATENT. —The extensive ignorance of the public in all matters relating to patents is very lamentable, and this is maintained and very greatly increased and rendered more difficult to enlighten, by the labours of, and opinions promulgated by, inexperienced, ignorant, and incapable amateur dabblers and others, who are so constantly found thrusting themselves forward with their crude and ignorant ideas and dangerous and ridiculous "advice" on the subject. The cost of a patent, like that of any other work requiring the exercise of skill, education, and experience, must entirely depend on the amount of work to be done in preparing proper documents and drawings. The Government fees do not—as the ignorant and inexperienced inventors or intending patentees so fondly imagine—cover any more than the charges at the Patent Office: in fact, they simply represent the stamps on a title-deed, a mortgage, an agreement, a lease, or other document which requires to be of a legal character in order to obtain legal support. An inventor or intending patentee may, of course, if he so chooses, do his own work himself and put in the papers he has prepared—just as a man may be his own lawyer, his own physician, his own architect, his own engineer, his own builder, or do any other work of the kind—and then the charge at the Patent Office for recording his application is covered by the £1 stamp, which he must have impressed on his petition. Then at, or before, the end of nine months from the date of his application he must file a complete specification and drawings, etc., embracing all the particulars required by the law to be done, to make a document the law will support, and on this there must be three impressed stamps of £1 each, so that when the patent is granted he has obtained what is generally considered by most inventors to be "a valuable exclusive privilege"; and all this, under these circumstances, for the moderate sum of four pounds! This will hold good for four years from the date of his application, at, or before, the end of which period he will have to pay the sum of £10—which will keep up the assumed right for another year; and at, or before, the expiry of the sixth year he must pay another £10; and in the same way each year up to the eighth, when the payment is raised to £15, which has to be repeated; and before the expiry of the tenth the payment is raised to £20, which has to be repeated before the expiry of each succeeding year it is desired to keep the patent in force until the thirteenth year is reached, when the last payment covers the fourteenth year; at the expiry of which the patent comes to an end, and then becomes the property of the public, unless an extension is obtained. If preferred, in place of the above, £50 may be paid before the expiry of the fourth year, and £100 before the expiry of the eighth, which payments keep the patent in force for the full term of fourteen years. We should never advise an inventor or intending patentee to trust to his own unaided exertions in preparing the title, documents, and claims required by the law to define his invention; nor would we advise him to trust himself in the hands of anybody but a really skilled, respectable, and capable adviser. At the present time we are swarmed out with a host of persons undertaking to "advise" inventors, and prepare their specifications, drawings, etc.; not a few of whom will be found to be foreigners—Jews as well as Gentiles—and whose thorough acquaintance with the English language, and the English patent law, must be obvious to any person of the least comprehension. Of what good is a useless and invalid patent to anyone, even if it is a gift? and if PATENT is an admirer of such things, he will be most successful in obtaining one by doing the work himself.—C. E.

**Negative Varnish.**—C. G. (*Putney*).—A very good negative varnish may be made by mixing one part of best white hard spirit varnish with two parts of methylated spirit and straining. If this is found to be too thick, add a little more spirit. It is rather long in hardening, but is, otherwise, a very good protection varnish. Another popular recipe is—to six ounces of best orange shellac, two ounces of sandarach, powdered coarsely, and mixed with as much roughly powdered glass (this is merely to expedite the solution by keeping the particles of gum separated), to a gallon of cold methylated spirit. Shake up daily for a week, let it stand to settle for a few days, then pour off the clearer portion and filter. This makes a rather dark-coloured varnish, but a very good and hard surface. Of course, with both kinds the negative requires warming *slightly* before and well after the application.—D.

**Illuminating Addresses.**—GUGLIELMUS.—All materials for illumination are to be bought from the larger artists' colourmen, such as Brodie & Middleton, 79, Long Acre; Lechertier, Barbe & Co., Regent Street; and Winsor & Newton, Oxford Street. The sizes and prices of vellum at the first-named shop are—10 in. by 8 in., 1s. 9d.; 14 in. by 10 in., 3s.; 16 in. by 12 in., 4s. 6d.; 18 in. by 14 in., 5s. 9d.; 25 in. by 19 in., 10s. 6d. I am not acquainted with any published designs for these things, the illuminator generally arranging his own design so as to be emblematical of the circumstances under which the address is presented; but if there are any such things in the market, they will be met with at such shops as those mentioned above. I believe that Martin Billing, Son & Co., Livery Street, Birmingham, print and sell vellum for the purpose with a border in *type* ornament, printed in two colours.—S. W.

**Pattern for Down Pipe over Plinth.**—J. G. (*Glasgow*).—If an order came to our foundry for a pipe to pass over the return plinth, such as you draw, having a 4 in. projection and a 4 in. rise, I should simply draw it and the pipe out to full size on a drawing-board, measure the angles A and B, and, setting a bevel to them, cut the pipe ends to suit. This is as simple a job as one can have. If I have misunderstood your query, please make it clearer.—J.



Rain Pipe.

**Carpenter's Rule.**—W. I. C. (*Tavistock*).—The eight square lines, or the lines marked E M (see diagram of rule), are for the purpose of converting a square into an octagon or eight-sided figure. For instance, if the square below is 8 in. square, and you want to turn it into an octagon, look down the line E on rule until you come to 8, then the distance from the outer edge of rule to 8 on the E line is the distance from each corner of the square to the points of the octagon, viz., $2\frac{5}{16}$. In exactly the same manner, if the side of the square measures 9 in., 10 in., 12 in., or any other size up to 36 in., the length from the corner or angle of square to the points of octagon is found on the front edge of the rule opposite the length of side of square on line E. The figures on the line M give exactly half the length of the side of the octagon required. If you now look at 8 on line M, you will find it is exactly $1\frac{1}{16}$ in. from the outer end of rule, which is the length of half the side of the octagon. This can easily be proved by a little attention. For instance, the side of our square is 8 in., the length from corner of square to point of octagon is $2\frac{5}{16}$ in.; therefore, if you add the two $2\frac{5}{16}$ in. together, this will give you $4\frac{5}{8}$, and the difference between $4\frac{5}{8}$ in. and 8 in. is the length of one side of the octagon, viz., $3\frac{3}{8}$ in., the half of which is $1\frac{11}{16}$ in. as above. Similarly as this line M gives the half of one side of an octagon, it also gives the means of determining at once the size of the piece of stuff required to get out an octagon on any given size. For example, divide the length of the given side by 2, find the result on edge of the rule and the size opposite on the line M, it will be the size of the piece of stuff required. For instance, an octagon is required with its faces each 12 in. $12 \div 2 = 6$, then find 6 in. on the edge of the rule (that, of course, is opposite 15 in.), and the size on the line M is the size required to get the octagon out of. There are sometimes three teeth on a carpenter's mortise gauge, two on one side for mortises, and one on the reverse side to enable the tool to be used either as a mortise gauge, or a single tooth or ordinary gauge. The majority of carving tools are sharpened in the way described in your letter.—E. D.

Carpenter's Rule.

**Polishing Rosewood and Inlays.**—S. S. (*Salford*).—As you can already polish plain surfaces, you ought to experience no difficulty in polishing the rosewood inlaid work. If you omit the "filling," which you seem to think is so necessary, especially if the work is well cleaned off and glass-papered quite smooth, it might be wiped over with a little clear linseed-oil, but this is a matter of choice. Instead of the usual brown polish, as made from orange shellac, use what is known as white or transparent polish. It will be necessary to give a few extra rubbers of polish in place of the "filling in," and it will be found an advantage if you give the work a few taps occasionally, as the "bodying in" proceeds, with a little powdered pumice tied up in a piece of rag or very fine muslin. It helps to fill up the grain and grind the polish to a level surface. The mahogany inlaid work will require a somewhat different procedure. As you wish to darken the mahogany, the light and coloured stringings must be protected by carefully coating them over once or twice with white polish, or equal parts white polish and white hard varnish, applied with a camel-hair brush, taking care not to put any on the part you wish darkened, as it will prevent the stain striking in. When this is dry, apply your stain, which, when dry, may be oiled and filled in if desired, but can with advantage be omitted. Unless you feel sure the inlays are well protected when polishing, give two or three good wet rubbers of polish to set the stain. When quite dry, glass-paper quite smooth; then body up, using pumice as advised. You will perceive that if the mahogany had been carefully selected as regards colour, or stained previous to using, the process of polishing would have been much simplified.—LIFEBOAT.

**Telescope.**—GANELON asks if articles have appeared on the construction of microscopes and astronomical telescopes, and, if not, for the necessary dimensions. If GANELON will procure Nos. 22 and 23, Vol. I., of WORK, he will find full instructions for a good microscope designed expressly for the readers of WORK. It has been a matter of gratification to the writer of the articles to know that the readers of WORK have in several instances worked from the design, and have expressed great satisfaction with the result. As far as I am aware, details for the construction of a telescope such as GANELON desires have not been given. I would just say that a 4 in. achromatic is rather an expensive O. G. to try one's skill upon as a first effort. However, I will give such brief information as is adapted to "Shop." The body tube may be about two-thirds or four-fifths of the focal length of the O. G., which we presume will be about 60 in. At a distance of half of the focal length of the O. G., a stop must be placed with an aperture of 2 in. The full length of the focus must be made up by a smaller tube to carry the focussing tube with the eye-piece. The Editor has in hand a short article on the construction of eye-pieces, giving the fundamental principles, which will enable anyone to construct one of any power. No doubt it will appear as soon as possible, when GANELON will find all the information he needs.—O. B.

**Xylonite.**—R. W. (*Blaina*).—The address of the Company is—The British Xylonite Company, Limited, 124, High Street, Homerton, E.

**Picture-Frame Clay.**—J. T. H. (*Bacup*).—The clay mentioned in Picture-Frame Gilding, Vol. III., No. 121, page 262, is prepared clay ground fine by machinery, and sold at any reliable artists' colourman's as "gilders' clay." There is no difficulty in getting this, as any of G. Rowney's agents will sell it at 9d. per lb.—H. E. M.

**Sensitised Paper.**—J. D. (*Hull*).—Albumenised paper is sensitised by floating it for three or four minutes on a solution of silver nitrate of about fifty grains to the ounce of distilled water, then drying in the dark, in a warm current of air free from gas or other noxious vapour or dust. When dry, the paper should be either rolled tightly or laid flat under pressure until required for use. The custom is in sensitising, after the paper has laid a sufficient time on the silver solution, to carefully raise it by two corners and draw it over a glass rod fastened to the end of the dish in order to remove the surface moisture as much as possible; the remaining moisture is blotted off with pure blotting paper. The sensitised paper is then hung up to dry. As to the preparation on dry plates that J. D. alludes to, it is an emulsion of bromide and iodide of silver in a strong solution of gelatine, for which there are many formulæ. The best plan would be to procure a hand-book on the subject. Abney's "On the Preparation of Gelatine Emulsions" is about the best; and make yourself thoroughly acquainted with the process.—D.

**Patentees.**—R. E. (*Bolton*).—Indexes to WORK, Vols. I. and II., can be procured of any bookseller, or of Cassell & Co., London, E.C. Price one penny —with postage, three-halfpence.

**Copying a Medal.**—H. H. (*No Address*).—We much doubt whether H. H. will succeed in making a satisfactory copy of the medal in question by *casting* in metal; he will find electrotyping a far superior method. Let him oil one side of the medal, but very slightly, so as not to fill up any of the depressions, tie a slip of stiff paper round the edge to form a rim, and having mixed *fine* plaster as thick as cream, pour it on to form the mould. The second side will be treated in the same manner. These moulds, when dry, should be rendered non-porous by laying them face downwards in melted wax. Their faces then need to be brushed over with black-lead, and they are ready for the bath of dissolved copper. If the copyist has no electrotyping apparatus, his better plan will be to hand his moulds to a professed electrotyper, and let him place them in his bath. This he will do for the merest trifle, as they will give him no trouble beyond simply hanging them in the solution of copper. But for small matters, such as medals, and for the use of copper only, all the needful apparatus may be set up for a few pence. The electrotyping process reproduces the minutest touches on the object copied with absolute fidelity. The shells of copper which will be deposited when removed from the moulds may be backed up with soft metal—lead with a little tin and antimony in it—either together or separately; and the faces can be bronzed in various ways, or, if desired, coated in the bath with a film of gold or silver.—S. W.

**Small Organ.**—G. W. O. (*Durham*).—The dimensions of the parts for the organ referred to in the answer to GOOD TIPS (see page 108, column 3, No. 111) are as follow:—Sound-boards, 3 ft. 9 in. long. Total width when joined together, about 16 in. Wind chest, same size, and 4 in. deep. Bellows, 3 ft. 4 in. long, 14 in. wide; middle board of bellows 3 in. longer, so as to rest on supports on building frame. Building frame, 3 ft. 9 in. long; same width as the two sound-boards, and about 3 ft. 6 in. higher, or a few inches higher if couples or pedals are required. As regards general construction, I should advise you to obtain one of the books on organ building which have frequently been mentioned in these columns. —M. W.

**Organ Building.**—C. W. T. (*Old Trafford*).—It would require too much space to give you all the information you require as to scales, thickness of wood, lengths, voicing, etc. Your best plan would be to purchase one of the books mentioned frequently in these columns, which would give you all the information you require on these points, and on other matters connected with organ building. Any reply which I could give in these columns would be too meagre to be of much service to you. —M. W.

**Wind Trunk for Organ.**—J. E. B. (*Smallheath*). —The wind trunk for your organ should not be less than 10 in. wide by 2 in. deep; if you have space to spare so as to make it 2 in. or 3 in. wider, so much the better. The pedal wind trunk may be about 10 in. wide and 2 in. deep if single; but if two are used, make them each 5 in. by 2 in. The length of these trunks depends entirely on the height of your building frame; they must be long enough to reach from the trunk band to the wind chest in each case. The manual wind trunk will be about 3 ft. 6 in. long, and pedal one about 16 in., but it is impossible to give the exact lengths. You can easily find them for yourself when you have constructed your building frame, etc.—M. W.

**Organ Pipes.**—F. B. (*Oldham*).—You are quite right; there is a slip in the reply to F. W. (*Sheffield*), at the top of page 220 (No. 118). It should read that the 16 ft. tone can be obtained from a stopped pipe 8 *feet* long, not 4 *feet*.—M. W.

**Watch Cylinder.**—SILVER WATCH.—When a horizontal escapement is at rest, the scape tooth may not always be in the same position, it may be inside or outside, or partly both; but in case, the distance the balance moves from the point of rest should be equal both ways. If it is not so, shift the collet (hairspring-collet) round until it is equal. Generally there is a dot mark on edge of balance and three on the plate; when at rest, the one on balance agrees with the centre one on the plate; the others coincide with the one on the balance when scape wheel drops off. The lever escapement is also the same, the balance moving equal distances from the point of rest, or may be made so by moving hairspring or roller.—A. B. C.

**Gilding on Glass.**—T. W. V. (*Leicester*). — Any communication you may make in the pages of "Shop" upon this subject shall have consideration; or you may send in an article, on approval, on the terms of payment usual with the journal.

**Brass Savings Bank.**—D. S. (*Glasgow*).— You must please state more definitely what kind of savings bank you require a design of, or if the pattern is left for the choice of the replier to your question. You seem to write as if you require a sketch of an existing article.—J. S.

**Electric Current from a Battery.**—P. R. (*Birmingham*).—The total volume of electric current obtainable from a battery is equal to its total electro-motive force divided by its total resistance. The total volume of current obtainable from it through work being done by the current will be equal to its total electro-motive force divided by *all the resistances* in the circuit. Hence, although the current volume of one cell may be the same as that obtainable from ten cells connected in series when taken by themselves, a far different result is shown when the resistance of instruments and of work placed in the circuit is added to the internal resistance of the battery cells. Suppose, for instance, we connect one cell to an ammeter having a resistance of ·005 ohm, we shall have to add this to the resistance of the cell, and the result will then be $\frac{1{\cdot}86}{{\cdot}08 + {\cdot}005} = 21{\cdot}88$ ampères, instead of 23·25 ampères. If, now, we connect ten cells in series with the ammeter, the reading should be $\frac{1{\cdot}86 \times 10 = 18{\cdot}60}{{\cdot}08 \times 10 + {\cdot}005 = {\cdot}805} = 23{\cdot}10$ ampères, because the ·005 resistance of the ammeter is divided among ten cells. Now, if you connect some accumulators in circuit with the ammeter and your 10-cell Bunsen battery, you must add the resistance of the accumulator cells to that of the Bunsen cells and ammeter, and also the resistance of the connecting wires. Now, supposing the resistance of the accumulator cells to be 8 ohms, that of the connecting wires, screws, and ammeter to be ·2 ohm, and the internal resistance of the battery cells to be ·8 ohm, then the current will be $\frac{1{\cdot}86 \times 10 = 18{\cdot}60}{{\cdot}08 \times 10 + {\cdot}2 + 8 = 9} = 2{\cdot}06$ ampères, and this agrees with the reading of your ammeter when charging is commenced. As the internal resistance of the accumulators increases whilst being charged, owing to the back electro-motive force of the charged plates, the current volume is lowered, hence, your ammeter then gives a reading of 1·5 ampères. I hope you will now clearly understand why the volume of current from your battery is reduced whilst connected to work being done by the current. —G. E. B.

**Rat Cage.**—J. H. (*Cork*).—Figs. 1 and 2 show a small cage open and closed for white rats or mice. It is really a wire cage made to slide in and out of a wooden box. To make such a cage, cut two strips of mahogany 3 ft. long by $\frac{5}{8}$ in. Cover one angle with tin; temporarily fasten the tin on; mark off half inches on the two sides covered with tin; then bore the holes for the wires with a strong bradawl through the tin into the wood. This will fasten the

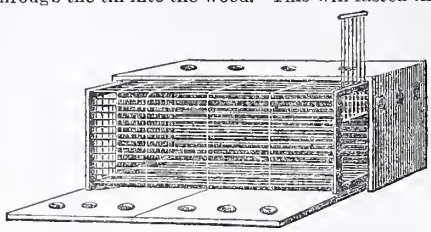


Fig. 1.—White Rat Cage (open).

tin on. Cut each strip into four, join them into two strong frames, and wire them as illustrated, leaving eight wires for the sliding door. Have four stout wires 18 in. long, and fix them into the corners of the frame. Make a box of $\frac{1}{2}$ in. deal an inch deeper than the wire cage, as per figures. The inch allowance will form a tray for the sawdust at the bottom of the cage. To clean the cage out, open the two doors in front, withdraw the wire cage, and knock

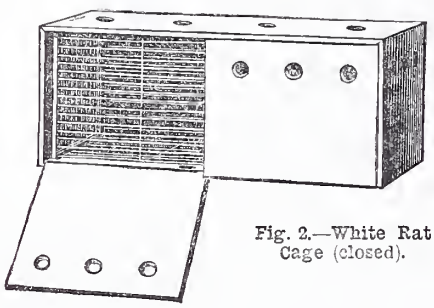

Fig. 2.—White Rat Cage (closed).

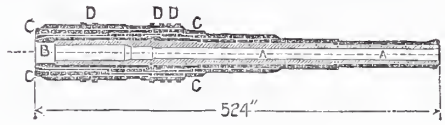
out the box. Sprinkle some fresh sawdust in the bottom, and replace the wire cage. To form a nest for the rats, a piece of wood is fastened inside the wires at one end; or, what is better, a little box can be made to fit the inside of the cage. This form of cage on a larger scale answers equally well for squirrels, and smaller, for white mice.—F. H.

**110-Ton Gun.**—LITTLE JIM.—The figure shows the 110-ton gun in section. It is constructed entirely of steel. Like all heavy guns made in this country, there are two essential portions, the inner tube and the outer section. In the figure, the inner tube is indicated with fine shading, and the outer portion with more open shading. The inner tube, A, is made of a single piece of Whitworth compressed steel. Over this is shrunk the breech-piece, B, and around this again are shrunk three layers of steel hoops, C. It will be noticed that all of the main hoops, as well as the breech-piece and the inner tube, are provided with shallow shoulders. The shrinkage of the hoops causes longitudinal



110-Ton Gun.

pulls against these shoulders, and their arrangement is such that there is a system of perfect and mutual resistance to longitudinal stress in each section of the gun. There are no trunnions. At D D a series of rings are formed on the outermost or "trunnion hoop." Three strong bands pass round between these rings and tie the gun to its carriage. The dimensions of the gun are as follows:—Total length, 524 in.; length of bore, 487 in.; length of rifling, 393 in.; diameter of bore, 16·25 in.; diameter of powder chamber, 21·125 in.; cubical capacity of chamber, 28,610 cubic in.; weight of gun, 247,795 lbs.; weight of powder charge, 960 lbs.; weight of shot, 1,800 lbs.; muzzle velocity, 2,128 ft. per second; total energy, 56,520 foot-tons.—J.

### V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—H. P. (*Leeds*); G. F. J. (*London, W.*); A. H. J. (*Norwich*); A. C. (*Leicester*); E. W. (*Halifax*); A. J. (*London, N.*); P. T. (*Birmingham*); W. P. (*Southport*); WATER; SOUTHPORT; H. F. (*Gateshead-on-Tyne*); J. M. (*Sutton-on-Hull*); J. H. # AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the **maximum of efficiency, combined with the minimum of cost.** This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their **Improved Eclipse Cameras and Outfits**, which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.**; or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above; also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.**; securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra.

These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.**, post free.

*A Wholesale Dealer's Stock-in-Trade at about Half-Price.*

J. H. S. & Co. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

Beecham's Pills

ARE universally admitted to be worth a Guinea a Box for Bilious and Nervous Disorders, such as Wind and Pain in the Stomach, Sick Headache, Giddiness, Fulness and Swelling after Meals, Dizziness and Drowsiness, Cold Chills, Flushings of Heat, Loss of Appetite, Shortness of Breath, Costiveness, Scurvy and Blotches on the Skin, Disturbed Sleep, Frightful Dreams, and all Nervous and Trembling Sensations, &c. The first dose will give relief in twenty minutes. Every sufferer is earnestly invited to try one Box of these Pills, and they will be acknowledged to be

## WORTH A GUINEA A BOX.

For Females of all ages these Pills are invaluable, as a few doses of them carry off all humours, and bring about all that is required. No female should be without them. There is no medicine to be found equal to Beecham's Pills for removing any obstruction or irregularity of the system. If taken according to the directions given with each box, they will soon restore females of all ages to sound and robust health. This has been proved by thousands who have tried them, and found the benefits which are ensured by their use.

For a Weak Stomach, Impaired Digestion, and all Disorders of the Liver, they act like magic, and a few doses will be found to work wonders on the most important organs in the human machine. They strengthen the whole muscular system, restore the long-lost complexion, bring back the keen edge of appetite, and arouse into action with the rosebud of health the whole physical energy of the human frame. These are FACTS testified continually by members of all classes of society, and one of the best guarantees to the Nervous and Debilitated is, BEECHAM'S PILLS *have the largest Sale of any Patent Medicine in the World.*

## Beecham's Magic Cough Pills.

As a Remedy for Coughs in general, Asthma, Bronchial Affections, Hoarseness, Shortness of Breath, Tightness and Oppression of the Chest, Wheezing, &c., these Pills stand unrivalled. They are the best ever offered to the public, and will speedily remove that sense of oppression and difficulty of breathing which nightly deprive the patient of rest. Let any person give BEECHAM'S COUGH PILLS a trial, and the most violent Cough will in a short time be removed.

Prepared only, and sold Wholesale and Retail, by the Proprietor, THOMAS BEECHAM, ST. HELEN'S, LANCASHIRE, in Boxes, 9½d., 1s. 1½d., and 2s. 9d. each.

Sold by all Druggists and Patent Medicine Dealers everywhere. *N.B.—Full Directions are given with each Box.*

### CARVED CASE FOR AMERICAN STRIKING CLOCK.

DESIGNED BY F. FAULDING.

THE ordinary case of a large American striking clock is by no means "a thing of beauty," as a glance at Fig. 6 (see page 387), in which a clock of this kind is shown, drawn on a scale of 1½ in. to 1 foot, will serve to show. Still, such a clock is a good timekeeper, and the sound of the hours, struck in succession on a wire gong in the form of a coil, is so soft and full and deep that it is worth while to withdraw the clock and its appurtenances in the shape of works, pendulum, pulleys, cords, weights, and dial-plate from the old case, and enshrine it in a carved case, for which a pretty and easily-worked design is afforded in Fig. 1. That there may be no mistake as to the kind of striking clock that is meant, it may be said that the wooden case, taking outside measurements, is 2 ft. 1½ in. high, its breadth, 15¼ in., the width of the casing in front, including the plain external frame and the intermediate moulding, is 3 in. Further, the width of the external frame and of the framing of the door is ⅞ in. From these, too, it is easy enough to reduce the other measurements, which it is unnecessary to give in detail. It will suffice to say that the object of the frame and moulding is to afford room for the weights, which work up and down behind them one on each side. The framing of the door, which is hinged to the intermediate moulding, as shown in Fig 6, is divided into two parts by a cross-bar, and there is a piece of clear glass in the upper part, through which the dial is seen, and a piece of painted glass in the lower part, consisting, in the clock from which the sketch shown in Fig. 6 has been made, of a small bunch of flowers—a tulip, a rose, some nondescript bloom, and two or three leaves, on a red ground. The case itself may be spoken of as being plain even to ugliness, and the art work on the door as meagre and unattractive in the extreme. Notwithstanding this, the clock itself, which has been doing good service for more than twenty years, is much liked, and its appearance is condoned for by its utility, the familiar sound of its gong, and "auld lang syne" combined. Perhaps many readers of WORK are possessed of such a clock, and may wish to transfer the works to a new and better-looking case; if so, a design for the new case is now placed at their disposal.

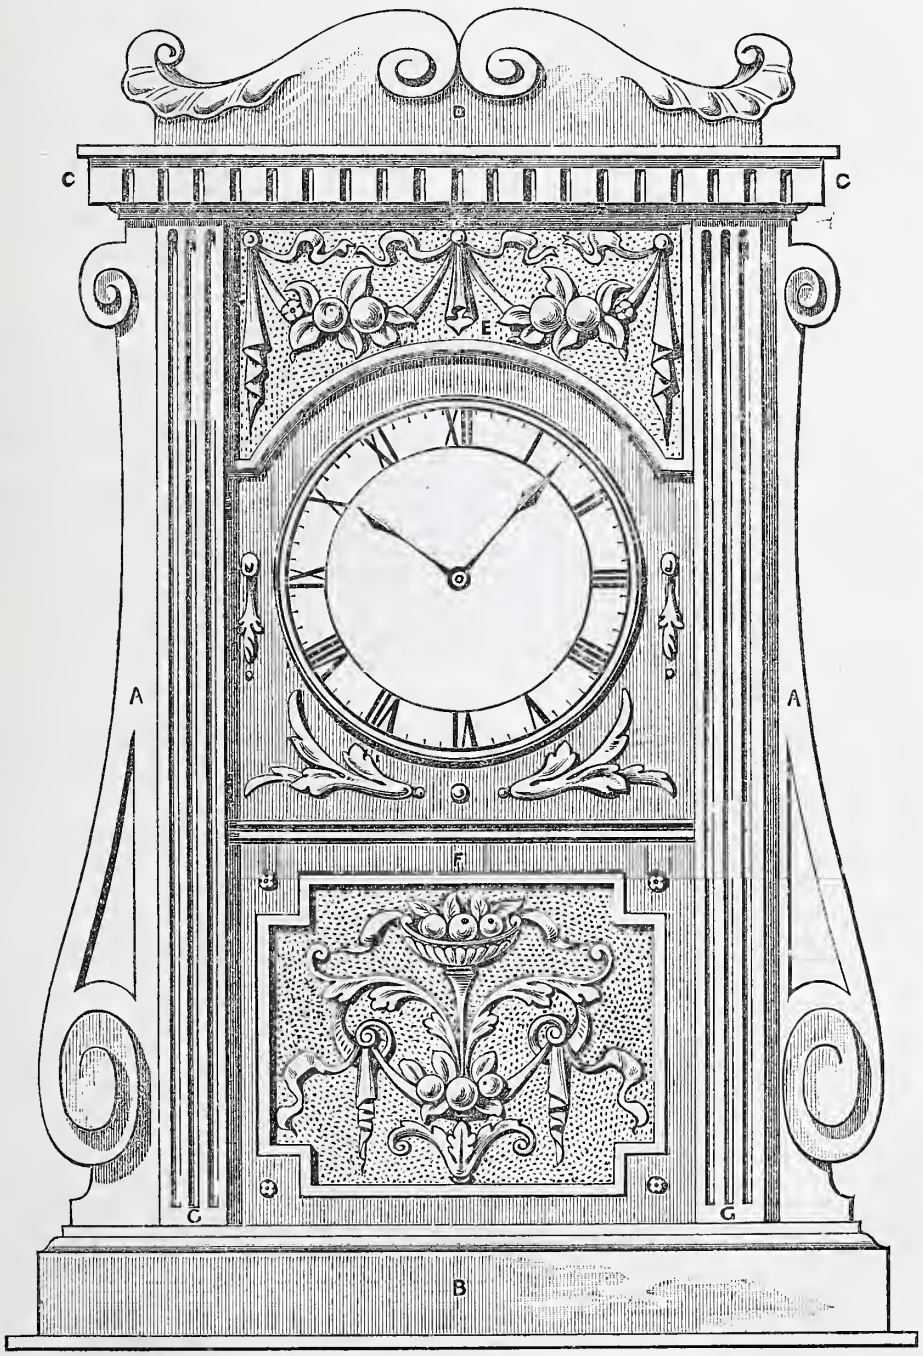

Fig. 1.—Design for Carved Case for American Striking Clock.

It must be understood, however, that the use of the design need in no way be confined to the large American striking clocks, of which one has been described in the above remarks. It may be modified by reduction to suit smaller clocks, and be made available for the small drum clocks which have to a great extent superseded the clocks with pendulums, etc.

With reference to the carved case represented in Fig. 1, it may be made in walnut or any similar hard wood. The size of the case must be determined by the size of the clock, and the first thing to be done will be either to make a new case, which will involve but little trouble and labour, or to get one made by a joiner or cabinet-maker, to whom the necessary instructions would have to be given respecting size. The case thus made would afford a basis or substructure on

which to fix the ornamental carving. The wood of which the case or cupboard is made should not be too thin—not less certainly than ½ in. stuff planed down; and possibly ⅝ in. stuff which would plane down to ½ in., or thereabouts, would be better. The brackets, A, A, shown at the sides in Fig. 1, should be dowelled or pinned to the sides of the casing, and the plinth, B, which must cover the entire bottom of the case, be screwed on from underneath. The cornice, C C, at the top should be treated in precisely the same way, and the pediment, D, blocked and glued to top side of cornice. The carving above the dial, shown on a larger scale in Fig. 2, will be best cut in a solid arch-shaped piece of wood ¼ in. thick, and then fixed on the upper part of the door, as shown in Fig. 1 at E. The carving below the dial, shown on a larger scale in the same manner in Fig. 3, should be attached to the door in the position indicated at F. Fig. 4 shows a section of the grooved or fluted pilasters, and Fig. 5 a section of the cornice. The pilasters, which are shown at G, G, are attached to the front edge of the case, and to a strip of wood fastened to the inside of the case, to afford a firm bearing for the pilasters. They form, with the cornice and the plinth, a framework for the door, which is hinged to the pilaster on the right-hand side. It is behind these pilasters that the weights will work up and down, as behind the broad moulding in Fig. 6. When the carving is completed it may have a finish imparted to it with wax or French polish, but the carved work should be left dull, and the mouldings only brightened in the manner described, as by so doing a superior appearance will be imparted to the whole of the work. Do not use any glass-paper in finishing the carving. Amateurs will sometimes do this, with the idea that their work will be improved thereby; nothing, however, tends to destroy the sharp and vigorous appearance of wood carving more than the employment of glass-paper in finishing.

Figs. 2 to 6 inclusive have been placed in the opposite page, as this arrangement is more convenient for readers.

I have omitted to mention that the dotted grounds shown in the carved parts at E and F are finished so as to present the roughened appearance indicated by means of any of the small punches that are used for this purpose. The end used for surfacing is generally fashioned into some form such as a trefoil, etc.

So much for the more ornamental and elaborate portions of the carved work of the clock-case—I mean those shown at E and F in Fig. 1—of which, after all, there is not so very much that involves what I may call carving proper, for the ornamental work in the pediment D, and at the head and foot of each of the brackets, A, A, is such as may be done by any woodworker of ordinary capacity; while the cornice, C C, and the fluted pilasters, C, C, present no difficulty whatever, or, at all events, ought not to do so, for the work in both of them is plain and straightforward, and in the latter case may be readily done by means of a scratch or router, which has frequently been mentioned and its construction described in Vol. I., page 101, of Work. Thus even to a workman of no great skill the only portions that should present any decided difficulty are the parts at E and F, and possibly the small carved pieces on each side of the dial and just below it.

Now the question is, how may this difficulty be surmounted by anyone who cannot, or will not, attempt the carving. By fret-workers it may be easily done, for a thin overlay of the forms indicated at E and F might be placed in the positions now occupied by the carved work, and pierced, or cut with a fine fret-saw in such a manner as to imitate very closely the patterns that are given in Figs. 2 and 3. In this case the edge of the overlay will represent the outer lines of the projecting parts that form the borders of the panels, the borders themselves being omitted. The pattern being cut out will appear as if sunk in the overlay, and the wood below will appear through it. Thus, an effect similar in some measure to inlaid work will be produced, and, if the door of the clock-case were ebonised, and the overlay were of thin white holly, or, better still, of xylonite, the semblance of inlaid work in ebony and ivory would be obtained. Another and perhaps a better way would be to cut out the carved work in outline in the flat, and the borders of the panels and other ornamental parts, at the sides of and below the dial, in xylonite or white holly, and attach them with glue to the woodwork below. Indeed, a very close resemblance to the actual carved work itself might be produced, if, instead of cutting or carving it out from the solid, the framing of the sunken parts and the carved pattern were cut out in wood of ⅛ in. in thickness by the fret-saw, and the edges sufficiently reduced and rounded, and the markings of the foliage and drapery sufficiently taken out by aid of a V-tool to remove all impression of the flatness that is inevitable if the cut-out pattern were put on in the solid; or, in other words, of uniform thickness throughout without any attempt at relief by the means of the V-tool and the simple tools used in chip-carving. It will be understood that when xylonite or any other material is used to gain the effect of inlaid work, the material should be as thin as possible, not thicker, in fact, than cardboard or Bristol board of tolerable substance. So much has already appeared in Work upon the subjects of inlaying and marquetry that these matters need not be gone over again here. Nor is it necessary to do more than refer the reader to the "Shop" pages of Work for all information as to materials, etc., for carrying out the present bit of woodwork.

## AN EASILY MADE FIXING TANK.

BY W. E. D., JUNR.

HYPO. BATH—ITS NECESSITY—BEST FORM—MAKING TANK—MATERIAL TO USE—SIZE—HOW MADE—CASE FOR TANK—DIPPER—COVER.

EVERYONE who has taken up photography knows that before the negative can be brought into the daylight and used, it must be placed in a hypo.-sulphite of soda solution; this solution must (or ought, if good work is to be done) be kept in a separate dish or tank; the question then arises, "What is the best form to use?"

In my opinion it is one in which the negative is placed in an upright position, as in the old wet-plate process the glass was let down into the silver bath, because in this position the silver, as it is fixed out, settles to the bottom of the tank, as well as other impurities, and this is not disturbed when other negatives follow, as in a flat dish; it is also easier to take out, and much less fear of breaking the film.

For a long time I used an old silver bath to hold the hypo., and found it answer fairly well, the chief fault being that I could only fix one negative at a time; so I resolved to make a larger one, and looking round for a material to use, I fixed upon gutta-percha, and have found it answer exceedingly well.

Suppose the reader wishes to make one to take half-plates as the largest size. I would recommend that the bath be just about the size for half-plates one way and quarter-plates the other—say, an inside measurement of 6⅝ in. × 3⅝ in. × 6 in. deep; it is as well to decide upon the exact size. Cut out paper patterns and take these to the shop, so that the gutta-percha can be cut from the piece to the proper size and shape, thus preventing any waste.

When you have the five pieces ready for making the tank, heat an iron red-hot, draw along the edge of one piece and the side of another, bring the two pieces quickly together, and by holding a little time until set they will be firmly fixed; if not, and they betray any tendency to spring apart, you may use small brads or screws, as you would in making a box. Proceed in the same way with the other side and end, then put the bottom on; when done, take the red-hot iron and draw along the edges of the join both inside and out: this will cause the gutta-percha to run and fill up any holes, thus making it perfectly water-tight; do the same round the heads of the screws or nails; you can then put grooves along the sides and ends to hold the different plates, fastening them on in the same way; then put on one side for a little time so that it may set.

Now make a wooden box to fit tightly round the tank: thin wood, such as ¼ in., will answer every purpose, but unless the gutta-percha is thick it will be better for some support, and by using thin it comes cheaper. Make the bottom of the wood box an inch larger all round: this gives greater stability.

A dipper, to put the plates in the tank and take them out again, will be found very useful. If you have one belonging to an old silver bath, this will answer perfectly; if not, take a strip about 7 in. × 2 in., either of gutta-percha, thin wood well covered with shellac varnish, or glass; a ledge to hold the negative should be cemented on at the bottom.

A cover to keep out the dust and partly prevent evaporation completes the tank.

Should any further information be required it will gladly be given through "Shop."

## ARTISTIC LITHOGRAPHY.

BY MISS ADA J. ABRAHAM.

### More about Chalk Work.

CHALK AND PEN ON STONE—CORRECTIONS AFTER ETCHING—HOW TO HOLD CHALK—MODE OF WORK ALWAYS PERCEPTIBLE IN COLOURED DRAWING—GROUP OF LEAVES—MIXED STYLE IN COLOURED WORK—INTELLIGENCE AND FEELING IN WORK—LETTERPRESS, WITH DRAWINGS—UNIFORMITY DESIRABLE IN SERIES OF DRAWINGS—WORKING WITH MAGNIFYING-GLASS.

THE student should feel that he grasps the stone with the chalk—that is to say, that he works into the grain of the stone.

In holding the pen, he may use it as lightly as he likes, as the ink flowing from it will do its own work on the stone; but with the chalk it is different, for he must use a certain amount of pressure, however light the tint may be: therefore the necessity of using light crayon-holders. (*Vide* paragraph on "Chalk," page 66, No. 109, Vol. III. of Work.)

There are times when corrections can be made after the stone has been etched by darkening tints with the chalk, but the artist should advise the printer that he intends doing so, that the stone may be most carefully prepared for him. He must remember in making alterations by stippling over chalk work not to do so too strongly, or to make the dots too large, as the tint already on the stone is most deceiving to the eye, and an otherwise good tint may be completely spoilt by the dots showing up when printed about three times the strength of the rest of the tint.

There are as many modes of working with the chalk as there are with the pen; in fact, more, as there is so much more scope for the student's artistic taste to have its bent. In drawing a sky, a flat point would be preferable to a fine round one, and by holding the chalk at the end of the holder make the lines as broad as possible; or don't show any lines at all, but put a tint on the stone with the broad chalk evenly and smoothly; in fact, almost rub it on, making it stronger at the top and gradually fade into the distance. Should there be clouds in the picture, these may be drawn in comparatively short, broad, *curved* lines fading at either end, which may be joined by and slightly crossed by others at a slightly different angle. When this is filled in a good effect is produced by the different treatment in working; but I really can only repeat myself, and say, in lithography, the same as in drawing or painting, the student must use his own artistic knowledge and taste, and know what style of work is necessary in drawing different objects; and if he persistently follows the elementary and necessary rules, the knowledge and experience will be gained by every succeeding piece of drawing he produces.

On looking at a coloured drawing which has been drawn with the brush and pen, the *mode* of work is invariably seen, whether the tint be broken, flat, or shaded, etc. For instance, anyone who understands lithography can immediately, on looking at a Christmas card, tell whether it has been worked in little lines or dots, etc. But in

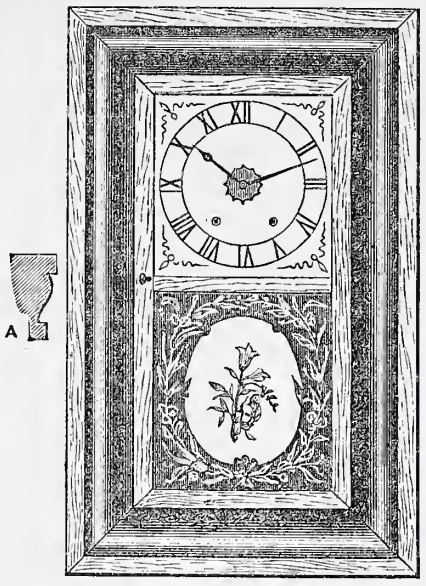

Fig. 6.—Ordinary Case of Large American Striking Clock—A, Section of Moulded Frame.

chalk drawings the style of work is not quite so easily detected, especially in colour printing. You can only see the effect, which certainly gives the drawing a much more natural and artistic appearance, although, from a commercial point of view, perhaps not so profitable, because of the necessity of printing from the original stones, on account of the difficulty in transferring good fine chalk tinting.

Take a group of leaves. In pen work they would be either stippled or drawn in fine lines, which must inevitably show when printed; but in chalk the tinting would be laid in in clear firm lines, with a broad point and the side of the chalk used; then, after crossing these at about an angle of 25° with lighter ones, still using the broad point, fill in any patches or spaces left with a fine pointed chalk. If this be printed in colour, a much more natural water-colour effect is produced. Of course, if a lot of colours are used, it considerably lightens the artist's work, besides the finer finish given to the drawing; but as everything nowadays has to give way to cheapness, we have to see how to obtain the best possible result with the fewest possible colours. By using a strong yellow, blue, or red, as the case may be, and shading it in such a manner that when the one colour is printed perhaps half a dozen different tones are produced, will naturally reduce the expense, instead of printing two or more shades of the one colour, which, in the above instance, is done away with by the artist's cleverness in execution.

Very often in coloured drawings the style of work may be mixed: that is, some of the colours worked with chalk, and others stipple, but it is simply an impossibility to say which means should be used for any special colour. I can only quote for example a good-sized landscape subject, with figures, etc., in the foreground. Now those stones on which the sky and distance are worked would be most effective done in chalk, whilst the figures, foreground, etc., would be best drawn in lines—stipple, splash, etc. But the student must not forget that should he be working a light blue stone, which would draw the sky, he must also draw the foreground in that colour in chalk, as the stone will be grained.

I trust I have not tired the student's patience in endeavouring to explain how to execute a good piece of artistic drawing, but I am sure he will understand how much I want to impress upon him the necessity of putting intelligence and feeling into his work, so that he may not fall into that fatal error of being a mere mechanical machine, which, unfortunately, is too often the result of any art requiring technical manipulation, and which in lithography consists in reproducing drawings and sketches by means of dots and lines.

After a drawing is completed, letterpress is sometimes required to be added at the foot of it; so to save an extra printing this is done by the draughtsman, and transferred to any one of the stones, whichever colour is most suitable: generally a dark grey or brown; but the artist must know where this is coming, and, if possible, not etch that part.

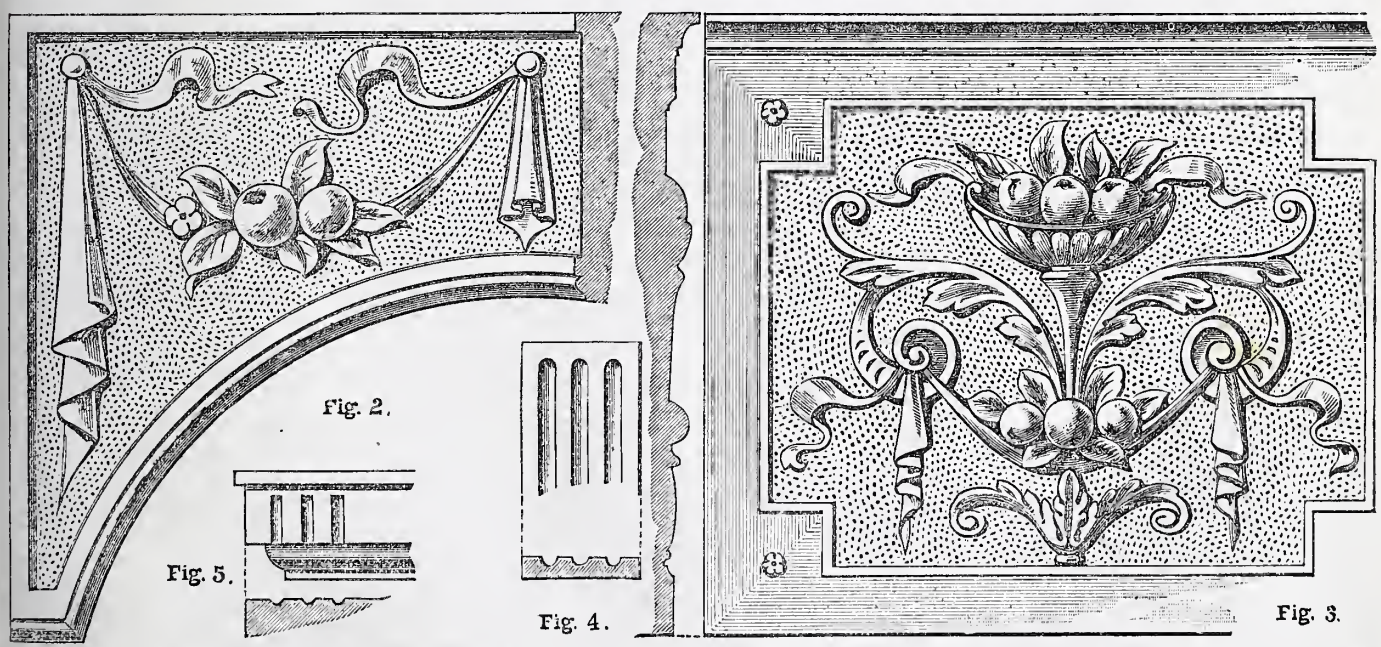

Fig. 2.—Half of Carved Arch at Top of Door as shown at E, Fig. 1. Fig. 3.—Carved Work on Panel at Bottom of Door, below Dial, as shown at F, Fig. 1. Fig. 4.—Top and Section of Pilaster at Side of Door. Fig. 5.—Section of Cornice above Door.

In arranging a series of small drawings on one stone, the student should try and get those of the same tone together, for he will see presently in practical work that it is not well to draw, say, half a stone with very heavy work, such as solids and strong tinting, and the other half with very fine line and stipple work. The drawings should, if possible, be uniform, or two different stones should be used. I do not mean those subjects requiring the gradations in shading from strong tinting or solid to the finer shades, such as the above diagrams; but where *one* drawing may require great depth, strength, and force in working, *another* may require to be very delicately and finely drawn; and as the etching for two such dissimilar pieces of work requires different treatment, which will be spoken of later, it would not be advisable to have them on the same stone, more especially as in the printing the former would require double the quantity of ink to the latter.

I must warn the novice against the bad habit of accustoming himself to work with a magnifying-glass, for if he does this he will get so used to it that he will only with great difficulty and force of will be able to do a fine tint without it, especially in stipple work; and it is unnecessary, I am sure, for me to point out the strain it would be on the eyes to continually look through glass.

In some fine work it is absolutely impossible to do it clearly and distinctly without: but as this is an exception, there is no reason why it should be made a practice, and after any such work is finished the glass should be entirely put away, and not brought out again unless the occasion requires it.

## BOILER EXPLOSIONS.

BY FRANCIS CAMPIN, C.E.

Classes of Boiler Explosion—Boiler Insurance—Phenomena arising from the Boiling of Water—Sudden Conversion of Airless Water into Steam—Fowler's Experiment—Explanation of Causes leading to Boiler Explosions—Defective Plates.

The failures of boilers by explosion or collapse may be divided into two classes: those in which the causes lie on the surface, and are, therefore, easily ascertained; and those in which the accident occurs under circumstances that do not admit of a clear explanation.

The former class of disasters may be prevented by care and intelligent supervision, such as is now rendered available to all steam boiler users by the Boiler Insurance Companies. They are due principally to two sets of causes: one is wear and deterioration by corrosion, and the other over-heating of flues, commonly arising from the deposit of scale.

To the unscientific observer the boiling and evaporation of water seems a very simple process, and one not at all likely to give rise to any surprises. This, however, is not the correct view, and it has long been known to physicists that under certain conditions the heating of water may lead to phenomena of an explosive character. It is well known that water has the property of absorbing and retaining considerable quantities of gases: hence water found in nature will be saturated with atmospheric air, and this air exerts a notable influence on the behaviour of water when heated, as it seems to aid its evaporation. Many years back M. Donny, of Ghent, found that water deprived of its dissolved air might be heated to a temperature of 360 degrees Fahr. before it entered into ebullition; it would then burst into steam with explosive violence, scattering the contents of the vessel containing it. For a reason which will subsequently appear, we call particular attention to the fact of the suddenly developed steam carrying the surrounding water with it. Of course, the whole mass of highly heated water is not vaporised, as a great quantity of the heat is immediately rendered latent by vaporisation of a part of it. The excess of heat over the boiling point is 148 degrees; and, as the latent heat of steam at atmospheric pressure is 967 degrees, only between one-sixth and one-seventh of the bulk of water could be evaporated at that pressure, though, of course, a smaller quantity might be generated at a higher pressure. The reason a smaller quantity of steam would be evolved at the higher pressure is because the water, keeping the same temperature as the steam, would not yield enough sensible heat to become latent. This explosive action has been pointed out as a possible cause of boiler accidents by some scientific authorities, especially in cases where fires have been banked up and the water unrenewed for some time; but on this point we shall have more to say.

A short time since Mr. F. G. Fowler, of Connecticut, U.S.A., made an experiment which tends to show that it is dangerous to use water containing air. According to this scientist, if water containing air is heated in a boiler until steam of low pressure—say, about 40 lbs. per square inch—fills it, and it is then inverted or shaken, the pressure will suddenly rise to about 80 lbs., and this, he thinks, indicates the cause of many boiler explosions. He accordingly advises us to discharge all the air from the water before feeding it to the boiler.

Taking these two statements as they stand, we appear to be in a dilemma, for whichever way we turn we are met by danger. One experiment shows that airless water is most dangerous to use, while another leads to the conclusion that the presence of air may lead to a catastrophe. Let us, however, look a little closer into these matters, and see if we cannot find some means of escape. We will go back to the case of the water from which the air has been discharged.

In the first place, it is to be noticed that the experiment is made under atmospheric pressure, 15 lbs. per square inch, so that when a part of the heated water bursts into steam there is no sufficient resistance to prevent it acting suddenly and carrying the remaining water with it; and, as water strikes a somewhat solid blow, a startling effect is produced. If, however, this water were in a boiler containing steam at 150 lbs. (absolute) pressure per square inch, the evaporation would proceed quietly, because there would be a resistance equal to the force of the fresh steam generated, or on the point of being generated; for while the temperature of the water and superincumbent steam are the same, evaporation will be suspended. Now, if we suppose the boiler pressure be allowed to run down to atmospheric pressure or thereabouts, and then rapid evaporation to commence, the steam thus evaporated, being confined, would rapidly rise in pressure and, of course, in temperature; and as soon as its temperature exceeded that of the water it would be condensed again, so that the pressure in the boiler could never reach 150 lbs.—that is, 135 lbs. above the atmosphere—so that actual bursting from over-pressure is hardly to be feared on this account.

There is, however, another view of the case. Water deprived of its air by mechanical means is in a different position from that deprived of air by heat in this respect, that when the air is removed in the former way the molecules of water come closer together, and, their mutual attraction becoming proportionately stronger, they require a higher degree of heat for their dispersion into vapour, and this dispersion will take place in a more vigorous manner. When, however, air is driven out of water by heat, it would seem reasonable to conclude that it is displaced by aqueous vapour, in which case no closer approximation of molecules will occur, and the water will evaporate at its normal temperature. If the case were otherwise, we might expect an explosion every time a boiler fire is lighted, as the air is driven off before the temperature of ebullition is reached. It is very obvious that water does dissolve or absorb steam in proportion to the pressure under which it is in contact with it; for if we draw water from a steam boiler into an open vessel a large quantity of steam will escape, and this steam is certainly not *generated* after the water leaves the boiler. If the water, after having been boiled, is allowed to cool so that air cannot reach it, it will, when cold, assume the condition of water from which air has been removed mechanically; but if air has access it will be absorbed, and the water will resume its normal condition.

Mr. Fowler's experiment of inverting or shaking up a boiler represents a state of affairs which can hardly occur except in a railway accident or a collision between steam vessels; but yet it has an interesting aspect, and further researches to determine the cause of the results reported would seem worth undertaking. A hypothesis might be hazarded that the air first expelled from the water carries up with it the vapour with which it is saturated at a temperature of 212 degrees, and remains in that condition in a stratum separate from the steam subsequently generated, and at a lower temperature. When agitation or inversion occurs, the air and its contained aqueous vapour will be raised to a temperature of 287 degrees, which will necessarily cause their expansion, and therefore the increase of pressure in the boiler. If this is the explanation, the trouble would cease as soon as the boiler gets to work, as the air entering with fresh feed water would all be heated up to the full temperature in passing through the water already in the boiler. If danger is anticipated, the first lot of air might be got rid of by blowing it off.

It has been suggested that boilers have been destroyed by sudden blows from the contained water due to its being carried up bodily by its contained steam on the occurrence of a sudden loss of pressure—such, for instance, as would happen if a plate gave way and released the steam instantaneously; but this is a case which is under control, as the primary cause is the defective plate. Taking the matter altogether, it seems that the causes of boiler explosions are getting to be pretty well understood by those whose speciality lies in that direction, and that before long what remains of mystery will be for ever cleared away.

Readers interested in this subject should read the papers on "Engine and Boiler Management," by Mr. M. Powis Bale, which are now appearing in Work, and which afford much useful information not to be found in a collected form elsewhere.

# DOVETAIL JOINTS.

BY FRED CROCKER.

TOOLS—COMMON DOVETAIL—SPACING—POSITION OF PINS—LAP DOVETAIL—SECRET DOVETAIL, LAPPED—SECRET DOVETAIL, MITRED—DOVETAIL HALVING—HALVING DOVETAILED BOTH WAYS—BLOCK APPARENTLY DOVETAILED ON FOUR SIDES.

DOVETAILED joints are used in a great variety of trades and materials, but the present paper will only apply to those used by the wood-worker. These consist of a taper mortise or socket on one piece (B, Fig. 1), and a pin or tenon on the other (A, Fig. 1).

*Tools.*—A detailed description of these will be scarcely required, as they are in general use for other purposes, but a small-backed saw, known as a dovetail saw, and a few bevel-edged chisels will almost be absolutely necessary.

*Common Dovetail.*—The most common form is used at the angle of two boards (Fig. 1). In making this joint, both edges are shot true and square; a gauge-line is run round one board at a distance from the end equal to the thickness of the other one, and the other board is treated similarly. Now, two methods are followed. Some mark and cut the pins first; others the sockets. In the first method (B, Fig. 1) you would have the pins carefully spaced, and the angles marked with the bevel; the saw would be run in down to the gauge-line, and the spaces between cleaned out with chisel and mallet. Then B would be put on the top of A, and the mortise marked with a sharp-pointed scriber. These would then be squared over, cut down to the gauge-line, cleaned out, and tried together. The second method is to first mark the sockets on A (sometimes on common work the marking is dispensed with, the workman using his eye as a guide); then run the saw in down to the gauge-line; put A on B, and mark the pins with the front tooth of the saw; cut the pins, keeping outside of the saw-mark sufficiently to allow of the pins fitting fairly tight; then both pieces may be cleaned out and tried together. In cleaning out the mortises and the spaces between the pins, the worker must first chop half-way through, then turn the board over, and finish from the other side, care being taken to hold the chisel upright, and not so as to cut under, as shown in Fig. 2, which is sometimes done to ensure the joint fitting on the

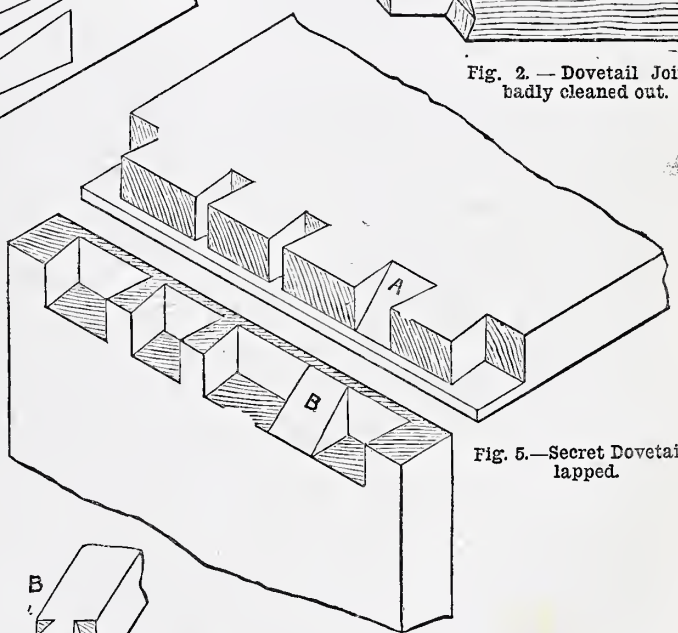

Fig. 5.—Secret Dovetail, lapped.

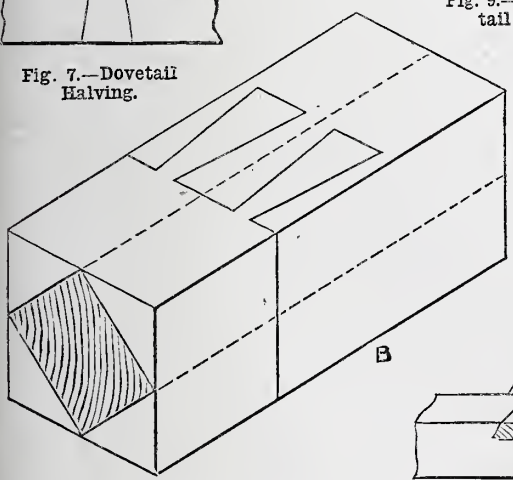

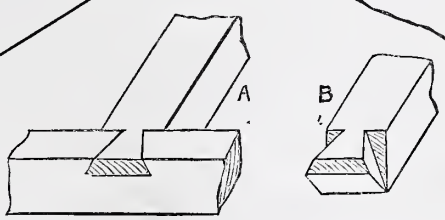

Fig. 8.—Halving Dovetailed both ways.

outside. Another bad practice is to leave the pins long, and rivet them over with the hammer when the joint is glued up.

*Spacing.*—The maximum strength would be gained by having the pins and sockets equal; but this is scarcely ever done in practice, the mortise being made so that the saw will just clear at the narrow side, the space being from eight to ten times the width of the widest side. Small pins are used for the sake of appearance, but fairly large ones are preferable. The outside pin should be larger than the others, and should not be too tight, or there is danger of its being split off, as shown at A, Fig. 3. In all dovetailed joints the angle should be slight, and not acute (as shown in Fig. 3). This looks strong, but is not so, as there is danger of the pieces, B, B, being split off in putting together.

*Position of Pins.*—When boxes are made the pins are generally cut on the ends, the sockets being on the sides. Drawers have the pins on front and back, the rule being to have the bevelled parts so that they are in opposition to the greatest stress that comes upon the piece of work to which the joint is applied.

*Lap Dovetail.*—Fig. 4 shows this joint, which is used for drawer fronts, the end grain being concealed on one side.

*Secret Dovetail, Lapped.*—Fig. 5 shows this joint, the end grain being almost concealed. The pin B is mitred, A being cut to correspond. This joint would be suitable for a work-box, the joint of the lid coming through B, so that when open it has the appearance of a mitred joint. This is a good form of joint, is more easily made than Fig. 6, and if, after gluing up, the edge be rounded, it equals it in appearance. In making this joint, first cut the pins, then the lap, and mark the sockets with the scriber.

*Secret Dovetail, Mitred.*—This joint (Fig. 6) is the most difficult to put together. The top pin is mitred right across, for the sake of appearance. In making this joint, both parts must have a lap or rebate cut on them, similar to the socket part of Fig. 5. Then the construction will be nearly the same, with the addition of mitreing.

*Dovetail Halving.*—This joint (Fig. 7) is objected to by some writers, because when A shrinks it will depend for its support on the screw, nail, or bolt, as the case may be. Then the dovetail form will be of no assistance in strengthening it, but will be a source of weakness at the shoulder, and the more the joint is bevelled the weaker it will be.

*Halving Dovetailed both Ways.*—Fig. 8 shows this. A gives the appearance, and the method of putting together may be gathered from B.

*Block apparently Dovetailed on Four Sides.*—This is shown at Fig. 9. A shows the block, and B the method of dovetailing. The pieces are dovetailed together with two pins, and then faced up to the smaller section shown on the end of B, which gives the appearance shown at A.

The two last-mentioned joints are of no practical value, but are rather curious. Many other applications of the dovetail are used, but cannot be described for want of space; but the columns of "Shop" are always open to the reader who requires advice. Amateur wood-workers are more disposed to nail ends of a box, for example, to sides instead of connecting them by dovetail joints. This may be all very well for rough work, but in joinery and cabinet-making the dovetail joint is much to be preferred.

## ANOTHER HINT ABOUT RAZOR STROPS.

BY OPIFEX.

In page 7, No. 105, of the present volume of Work, P. B. H. gave some very useful hints on the subject of stropping a razor which should prove acceptable to many, as we may safely say there is no mechanical process—except the use of a knife and fork—in which so great a number of men are daily engaged all the world over. And yet, as far as my observation goes, comparatively few know how to perform this simple operation to the razor's advantage.

The wonder is that so many razors shave at all, and the credit of their doing so is certainly due to the makers of the instrument rather than to the users in the great majority of instances. With regard to the use of the strop described by P. B. H., little can be added to his remarks; the only exception I take to them being that he recommends "flour of emery" to be applied to the strop, for if the ordinary flour emery of commerce be thus used, the result will be disastrous to the razor. The fact is that nothing but the most perfectly levigated flour of emery should ever be used upon a strop.

My object in writing, however, is to suggest that neither P. B. H.'s strop, nor the common strop of leather, etc.—used by

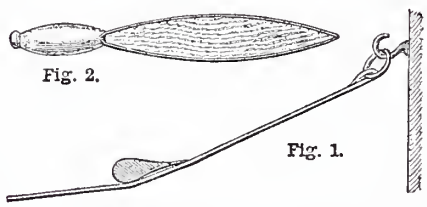

Fig. 1.—Diagram showing Section of Razor as applied to Barber's Strop. Fig. 2.—Convex Surfaced Razor Strop.

barbers—is suited for the purpose of sharpening or keeping a razor sharp, as both, but especially the latter, tend to thicken the edge of the instrument, and thus to detract from its cutting power.

The edge of a razor being formed by grinding both sides of the blade upon a wheel until the portions of the sides which form the edge are the nearest thing possible to being parallel without being actually so, it follows that, in order to preserve the shape of the blade as finished by the maker, it will be necessary to apply it to an abrading and smoothing surface, which shall correspond in some measure to the shape of the surface which originally formed it—*i.e.*, a wheel.

Now, this is exactly what the ordinary strop, whether rigid or flexible, does *not* do. In the former case the concave surface of the blade is applied to a flat surface; in the latter the edge bears upon a surface which forms an obtuse angle with it, as shown in Fig. 1.

Anyone who inspects the edge of a razor through a strong magnifying-glass will see that it consists of irregular teeth, like a very jagged saw, and will be able to appreciate the effect produced by either of the methods alluded to.

By frequent stropping these teeth are bent from side to side, until they are eventually broken off, and the edge becomes smoother, but considerably thicker, and, therefore, comparatively blunter.

To obviate this result, I suggest the use of a strop (about sixteen inches long, including the handle) shaped as represented at Fig. 2. The "body" of the strop is of mahogany, and is covered with finest buff leather or buckskin—in my case made from one of an old pair of braces; it is coated on one side with finest jeweller's rouge and blacklead, made into a paste with suet; the other side is the plain leather. Use it as directed by P. B. H. in the article already quoted; I have done so every day, with very rare exceptions, for ten years, and have never had my razor ground or "set" in all that time, because the original edge has been *preserved.*

## THE ZITHER: HOW TO MAKE IT.

BY R. F.

Introduction—Wood—Patterns—Construction of Instrument—Various Parts—Fitting of Parts—Gluing Parts Together—Bridges—Finger-Board—Marking Frets—Cleaning up and Feet—Pins and Wrest-Pins.

How well I remember the first time hearing a zither played! I was staying at a London hotel during the Exhibition of 1871, and in the small hours of the morning was awakened by the strains of "She wore a wreath of roses!" most exquisitely played. What manner of instrument was being used I had no idea, and thought at first it was one of those delicate musical-boxes with reeds; but, from the expression used and the subdued accompaniment so unattainable by mere mechanism, I was soon led to alter my opinion, and the introduction of an addition to the melody decided me that someone of the *genus homo* was concerned in its production. Inquiry in the morning disclosed the fact that "Julius," the night attendant, was wont thus to beguile the weary hours, and soon I had the satisfaction of examining the instrument, whose strains had so captivated my fancy a few hours before. A desire to possess one was soon followed by its acquisition, and an idea of improving upon it led me first to try and construct one. Since then I have made several, which have turned out very good instruments; and I therefore feel quite justified in giving my experience for the benefit of those readers of Work who care to "go in" for one, promising them that if they follow my instructions, they will be able to produce an article alike creditable to themselves and satisfactory as a musical instrument, and, bearing in mind always the maxim, that "Whatever is worth doing, is worth doing well," not being satisfied with anything short of perfection. That the attainment of such a standard is highly problematical I am prepared to admit, but that need not deter the worker from doing his very best. In this paper I do not pretend to give the orthodox methods of construction, but the easiest and most suitable for amateurs, and which I trust will prove as successful in the hands of any who may take it up, as they have done in my own case.

First, for the requisite wood, you will require 2 ft. of the best Swiss pine for the back, $\frac{3}{16}$ in. by 12 in.; a piece of mahogany, rosewood, or another piece of pine of the same thickness for the belly; a strip of maple or sycamore, $\frac{3}{16}$ in. by $\frac{7}{8}$ in., and 24 in. long, for the ribs on the curved side; another piece of the same for the straight side, 19 in. long; a piece of pine for the stays, 15 in. long by $\frac{3}{4}$ in., and about 3 in. wide; a piece of beech for the blocks, 10 in. long, $\frac{3}{4}$ in. thick, and 5 in. wide; a piece of ebony, 13 in. long, $\frac{3}{16}$ in. thick, and $2\frac{1}{4}$ in. wide, for the finger-board; another piece of the same,

7 in. long and 1 in. wide, from which to get out the upper bridge; a piece of ebony or rosewood, $\frac{3}{8}$ in. thick, 1 in. wide, and $8\frac{1}{2}$ in. long, for the lower bridge; and a small piece, from which to make three knobs for feet. Rather a formidable-looking list for such a small instrument, but nothing so very alarming after all, when the quantities of each are considered. Note particularly that all the *thicknesses* here given, with the exception of the stuff for the stays, are for finished material, as it will be required; but lengths and widths are given a little more than wanted, to allow for working. In addition to the stuff necessary for the instrument itself, you will require a piece on which to build, unless you prefer to use your bench-top for the purpose. This piece must be 24 in. in length and 18 in. wide; any thickness not less than $\frac{3}{4}$ in., and must be planed true on one side; and, lastly, a piece of $\frac{3}{4}$ in. by 6 in. wide, and 24 in. long, for a mould for the curved side; and a few more odd pieces of $\frac{1}{2}$ in. stuff, which will be mentioned as we go along.

Commence by getting out a stiff paper pattern from Fig. 1, and cut this out. Cut off $\frac{1}{4}$ in. from the bottom edge; then turn it over, and on the reverse side mark the position of all blocks, stays, and the sound-hole, as shown at Fig. 2; cut the sound-hole out, and your pattern is ready. Now take the pieces intended for the back and belly, which have been reduced to the thickness previously given, and mark on them all round the pattern; cut these out, and shape them up exactly alike, leaving the edges perfectly square. Lay the back on one side, and, taking the belly, lay it face downward on the slab or bench, and fasten it there by two screws, through the place where the sound-hole will be. Put these screws through another piece of wood, about $\frac{1}{2}$ in. thick and 2 in. wide, first, as the belly itself is not strong enough. Now take your piece of beech, 5 in. by 10 in. by $\frac{3}{4}$ in., and lay your pattern on, and mark along the top; then shift it $2\frac{1}{2}$ in. lower, and mark again; then mark off $\frac{3}{16}$ in. from each end, and this will give the pattern for the wrest-pin block, A, Fig. 7; and from the remaining piece can be got the lower block, $1\frac{1}{2}$ in. by 8 in., B, Fig. 7. Square the edges of these, and lay the upper block in its place at the top of the belly, flush with the top edge, and leaving $\frac{3}{16}$ in. at each end for the ribs to come on. Now lay the lower block in its place, and mark where the end of the curved rib will come; then cut a piece $\frac{1}{2}$ in. deep and $\frac{3}{16}$ in. wide out of the end of the block, for the end of the rib to fit into, as shown at Fig. 2. This block is now ready, and both it and the top one may be glued into their places, and weighted down till dry. When doing this, take care that the $\frac{3}{16}$ in. of the belly are left at *each* end of the upper block, but at the straight end of the lower block only. Before these blocks are glued on, you must be careful to have them well warmed, and also take care that your glue is perfectly hot, clean, and strong, but not thick. While they are drying you may get out your two diagonal stays, the shape of which is shown at Fig. 4, and a section in its centre at A′. These, you will observe, taper off to nothing at each end, and go quite across the belly, the lower one starting from a point $5\frac{1}{2}$ in., and the upper one $10\frac{1}{2}$ in., from the bottom on the straight side, and being carried across to points, $2\frac{1}{2}$ in. lower, on the opposite side. They should be $\frac{1}{2}$ in. deep in the centre, and $\frac{1}{2}$ in. wide throughout. They may be glued on, and cramped down by a button at each end, and by the piece that is already holding the belly down to the board being taken off, and its position altered, of course, using longer screws for this purpose. Fig. 8 shows this arrangement at A. The next parts to get on are the ribs, and for this a mould is required. The piece of wood, 6 in. wide, 24 in. long, and $\frac{3}{4}$ in. thick, will be required for this. On it lay the curved side of your pattern, and mark along its edge; then cut it out, and clean up the *hollow* side, and, taking up the buttons from the ends of the stays, screw this down side by side with, and exactly fitting, the curved side of the belly. The remaining piece can be screwed down at the straight side, and you will then have the belly in a mould. On the top of these pieces screw buttons of wood, about 2 in. long and 1 in. wide, at intervals of 3 in., and the arrangement is complete.

Before gluing in the ribs, it is as well to see that everything fits properly. Take, therefore, the slip you have prepared for the ribs, and reduce it to $\frac{3}{4}$ in. wide; then insert one end in the groove in the lower block, and gently bend it round the curved side, screwing the buttons down on to it as you proceed. If the wood is harsh or brittle, it will be as well to damp it before doing this. Mark the places where the ends of the diagonal stays come; take the slip out again, and cut out the little pieces that may be necessary; then replace it, and fit accurately. The straight side must be fitted in the same manner; and when this is done, the ribs may be glued in and cramped down, and the whole be left to dry (Fig. 8). The interior construction is now nearly complete, requiring only the addition of the long stay or inner bridge, C, Fig. 2. This is $13\frac{1}{2}$ in. long, $\frac{3}{4}$ in. deep, and $\frac{5}{8}$ in. thick, and must fit tightly between the top and bottom blocks. Two curved pieces are cut out of the under edge to give lightness to it, and two square pieces out of the upper edge to receive the diagonal stays; and if the blocks are thoroughly dry, this long stay may be glued into its place. Another interval for drying, and the cramps may all be taken off, the shell taken out of the mould, and the sound-hole cut. This is $3\frac{1}{2}$ in. in diameter, and must have its edges neatly rounded. A straight-edge must now be passed over the blocks, ribs, and stay, to see that all are exactly level, and any inequality must be rectified. When all is ready, the back may be prepared for fixing. Glue a small block, 1 in. square and $\frac{1}{4}$ in. thick at the widest part of the inside of the back, $\frac{3}{16}$ in. from the edge; this is to take the stem of a foot that will afterwards be fastened in. Mark on the outside of the back where the centre of this block comes. Now replace the shell in the mould, and refix the buttons in their places, turning them to one side to leave the top edges of the ribs bare. All being ready and your glue quite hot, pass a warm flat-iron several times over the blocks to get them warm; then glue quickly all the points of contact with the back—*viz.*, the blocks, the edges of the ribs, and the feet of the long stay; and, as soon as this is done, clap the back on, and weight down at top and bottom; turn the buttons into their places, and screw down. As this operation of getting on the back is a very important one, it being absolutely necessary that the contact with all the points should be perfect, it is better not to attempt it by one's self, but to get a little assistance. When all is quite dry, the instrument may be taken out of the mould, the edges cleaned up, and, with the back and belly, thoroughly smoothed with glass-paper. When this is done, prepare the bridges and finger-board. First cut out your upper bridge from the piece of ebony, 1 in. wide and 7 in. long. This bridge, when finished, is $\frac{3}{8}$ in. wide and $\frac{5}{16}$ in. thick, and has a small groove cut in at a distance of $\frac{1}{8}$ in. from the front edge, to take a piece of No. 18 brass wire, over which the strings are to pass. This is the pressure-bar, A, Fig. 5. Glue this bridge on with its bottom edge $2\frac{1}{8}$ in. from the top edge of the wrest-pin block, and its left end $2\frac{1}{8}$ in. from the straight side; the remaining distance to the edge will be occupied by the finger-board. The lower bridge may now be got out of the piece of ebony or rosewood, 1 in. by $\frac{3}{8}$ in. by $8\frac{1}{2}$ in.; and this, when finished, should be of the exact size and pattern as shown in the drawing D, Fig. 6, and the exact length of the straight part at bottom of instrument. The strings do not pass *over* this bridge, but partly over and partly through it—over it as far as the pressure-bar, and then through channels to where the bridge joins the top edge of the belly. The first five channels are cut at intervals of $\frac{3}{8}$ in. from each other, leaving $\frac{5}{16}$ in. of the finger-board on the outside of the first and fifth strings respectively; then a further interval of $\frac{1}{8}$ in., and divide the remainder of the bridge, leaving $\frac{1}{4}$ in. at the bass end, into twenty-six equal parts. These marks, which will be about $\frac{7}{32}$ in. apart, must be sawn through diagonally (as shown in Fig. 6) from the pressure-bar to the belly, and the lower of the channels thus made must be wider than the others, as the strings going through them will be thicker. It is better, perhaps, to glue the bridge on (leaving $\frac{1}{4}$ in. projecting over the end), and let it dry before cutting through it, as it is less liable to fracture then. The finger- or fret-board may now be taken in hand. This, when finished, should be 13 in. long, $2\frac{1}{8}$ in. wide, and $\frac{3}{16}$ in. thick. At a distance of $\frac{1}{4}$ in. from the top draw a line across, and on this line cut a groove $\frac{5}{32}$ in. deep. That is exactly half-way through the board. In this groove insert a piece of sheet brass or German silver, which must project $\frac{1}{8}$ in. above the top surface. This forms the nut, and from the *front* edge of this all the distances for the other frets are measured. Directly at the back of this nut five holes are drilled, sloping to the left, in which to insert the nut pins. These holes correspond to the five channels in the lower bridge, in being $\frac{3}{8}$ of an inch from each other. Now you may proceed to mark off the finger-board for the frets, the distances here given being from the *front* edge of the nut to the *centre* of each fret, so that the mark must in each case be cut out:—

| | |
|---|---|
| 1st.—$\frac{7}{8}$ in. | 16th.—$9\frac{3}{16}$ in. |
| 2nd.—$1\frac{1}{16}$ in. | 17th.—$9\frac{5}{16}$ in. |
| 3rd.—$2\frac{7}{16}$ in. | 18th.—$9\frac{7}{8}$ in. |
| 4th.—$3\frac{3}{16}$ in. | 19th.—$10\frac{3}{16}$ in. |
| 5th.—$3\frac{1}{2}$ in. | 20th.—$10\frac{3}{8}$ in. |
| 6th.—$4\frac{7}{16}$ in. | 21st.—$10\frac{3}{4}$ in. |
| 7th.—$5\frac{1}{16}$ in. | 22nd.—11 in. |
| 8th.—$5\frac{5}{8}$ in. | 23rd.—$11\frac{1}{4}$ in. |
| 9th.—$6\frac{3}{16}$ in. | 24th.—$11\frac{1}{2}$ in. |
| 10th.—$6\frac{11}{16}$ in. | 25th.—$11\frac{11}{16}$ in. |
| 11th.—$7\frac{3}{16}$ in. | 26th.—$11\frac{7}{8}$ in. |
| 12th.—$7\frac{5}{8}$ in. | 27th.—$12\frac{1}{16}$ in. |
| 13th.—$8\frac{1}{16}$ in. | 28th.—$12\frac{1}{4}$ in. |
| 14th.—$8\frac{1}{2}$ in. | 29th.—$12\frac{7}{16}$ in. |
| 15th.—$8\frac{7}{8}$ in. | |

When all are marked, proceed to cut carefully each one to $\frac{3}{32}$ in. deep, except Nos. 23 and 25, which are short frets, and only go half-way across the board. For this purpose a very fine dovetail saw must be used. Having cut all the grooves, fill in each one with a piece of the same metal, as

previously used for the nut, allowing $\frac{1}{16}$ in. only to remain above the surface. To fasten these frets in their places securely, take a small quantity of shellac, crush it to powder, and place a little in each groove, then heat the fret by holding it in a flame, and place it quickly in position. Note, do not make it red-hot, or it will burn the shellac instead of melting it. The rough edges and the ends of these must be rounded off, and the dots or stops may be inserted. These are for a few hours to dry. The whole may now be thoroughly cleaned up; the holes bored in the back for the insertion of the feet, one at top and one at bottom of straight side, and one at the widest part of the curved side, where you have a block ready for it. These feet are small round knobs, $\frac{1}{2}$ in. in diameter, with a stem $\frac{1}{4}$ in., and when in position have a sharp little spike of iron projecting from the bottom, to prevent the instrument slipping about on the table when with those of the other, and the whole sloping slightly to the top of the block. After boring they should be slightly countersunk. The bridge-pins of the accompaniment strings are $\frac{7}{32}$ in. apart, and slope to the right. All these bridge-pins should be made of No. 20 brass wire, and be $\frac{5}{8}$ in. in length, with $\frac{1}{8}$ in. left above the bridge. The holes for them should be drilled, not bored. The wrest-pins are of a special kind, and can be bought for a small sum. They can be had either

of ivory or pearl, $\frac{3}{16}$ in. diameter. Two are inserted half-way between the fourth and fifth, the eighth and ninth, the eleventh and twelfth, and the eighteenth and nineteenth frets; one on each side of the board; and one between the fourteenth and fifteenth, in the centre. These dots are guides to fingering (Fig. 1). The board may now be placed in position. First, warm it well; then glue it over, and quickly lay it in its place, giving it a rub up and down to set the glue, and taking care that the nut is level with the groove in the upper bridge, and the outer edge flush with the straight side. Clean off the glue that has squeezed out, and set aside being played. The back and ribs may now be stained and the instrument polished, unless you wish to try your hand at purfling. In this case you will require a purfling chisel and about 4 ft. of purfling, to go round the curved side and the sound-hole. When polished, the wrest-pin block may be bored. First, bore the holes for the melody strings. A reference to Fig. 1 will show where these are to be, and care must be taken that they are a little to the right of the holes for the nut pins. The pins for the accompaniment strings occupy the centre portion of the block, are $\frac{7}{16}$ in. apart, and are placed in two rows, $\frac{3}{4}$ in. apart, the pins of one row alternating in blue steel, polished steel, or nickelled. Messrs. W. J. Chilvers & Co., St. Stephen's, Norwich, supply them, as well as all other fittings, strings, etc. The work now remaining is the insertion of the hitch-pins, which are shown at E, Fig. 6. The lower row consists of the first five strings only, and are put in in a straight line, the other two rows alternate with each other, and the whole corresponds to the thirty-one channels through the lower bridge. These pins are made of No. 17 wire, are $\frac{5}{8}$ in. long, and are driven into the block for $\frac{1}{2}$ in. Now fit a piece of the No. 17 wire into the groove in each bridge, and the instrument is ready for

stringing. In stringing, take care to turn the pins to the left, as all the tuning is done with the left hand, when the instrument is in use. To learn to tune the zither it is necessary to have a scale, and these are always to be found in good instruction books. Procure one of these, and study it attentively.

## WIRE-WORK IN ALL ITS BRANCHES.

BY JAMES SCOTT.

THE WORM BLOCK—TYING—FRAMES—KNUCKLES.

SPIRAL springs are extensively used for various purposes, such as for salad or vegetable ladles, etc. They are usually made by the aid of an article called a "worm block." In Fig. 70 I have shown the appearance presented by such an adjunct, which is, in this diagram, supposed to be rigged up with the intention of being secured in a convenient position on the bench, although frequently it will be observed that the block is fitted to a very plain framework, with no view of being secured to the bench, but in order that it may be fixed to the vice when required for use, and always be regarded as a loose tool. Of course, the reason for this being the case in some shops is obvious enough: where a bench has several machines or tools upon it as fixtures, there is likely to be far less clear space for the workman than would be considered by him to be necessary; and, further, such tools, etc., as fixtures, would always be exposed to sundry knocks from the wire-work under manipulation, and, perhaps, in this manner receive more damage than would be the case were they made so that they might be placed underneath the bench during the non-requirement of them.

The worm block which I inspected was composed of a hard wood. It was about 7 in. or 8 in. long, 3 in. or 4 in. thick at one end, tapering to a point, as shown in Fig. 70, at the other end. Beginning at the point, a groove was worked around it completely to the other end, thus making a worm or spiral line upon it. Wires of various gauges can be used, provided the groove is, of course, made deep and wide enough for the purpose.

If to be fastened to the bench, it should be mounted upon standards, as shown. For these there will first be a H iron foot, with screw-holes in it. At each side there will be a support in the shape of a perpendicular iron rod, the bottom end of which will be welded into the foot, while the top end will receive an end of the handle-bar. Of the handle-bar I have not previously spoken. It will be an iron rod, bent as in Fig. 71, and driven through the middle of the worm block in such a way that there will not exist the remotest possibility of the latter working at all loose. That this should be the case is a very essential matter.

For the better utilisation of the machine, it will be advisable to firmly fix a wooden handle over the proper part of the handle-bar.

The ends of the uprights which are to receive the handle-bar will be bent as in Fig. 72. At each side, in addition, will be a half-circular iron rod, the top of which will be as in Fig. 73: so made in order that it may receive the perpendicular supports, and thus tend to strengthen the machine without creating inconvenience by arousing any possibility of the wire being worked getting entangled in any way.

If it is desired that this machine shall be a loose article, nothing more than a simple frame, after the pattern shown in Fig. 74, is required; for, attached to such a frame, when use were being made of it, it could be screwed up tightly in the vice by one corner.

At the pointed end of this block, at about the spot indicated in Fig. 70, will be a small hole, across the opening of which will be a little staple or piece of wire, as in Fig. 75. When the wire is about to be bent to the form of a spiral, the swift upon which the coil is placed must be fixed in a handy position for working from. One end of the wire is then hooked to the catch described in the point of the worm block, and guided in the groove. It will require little intelligence to perceive now how, when the handle is turned—the wire, of course, being properly

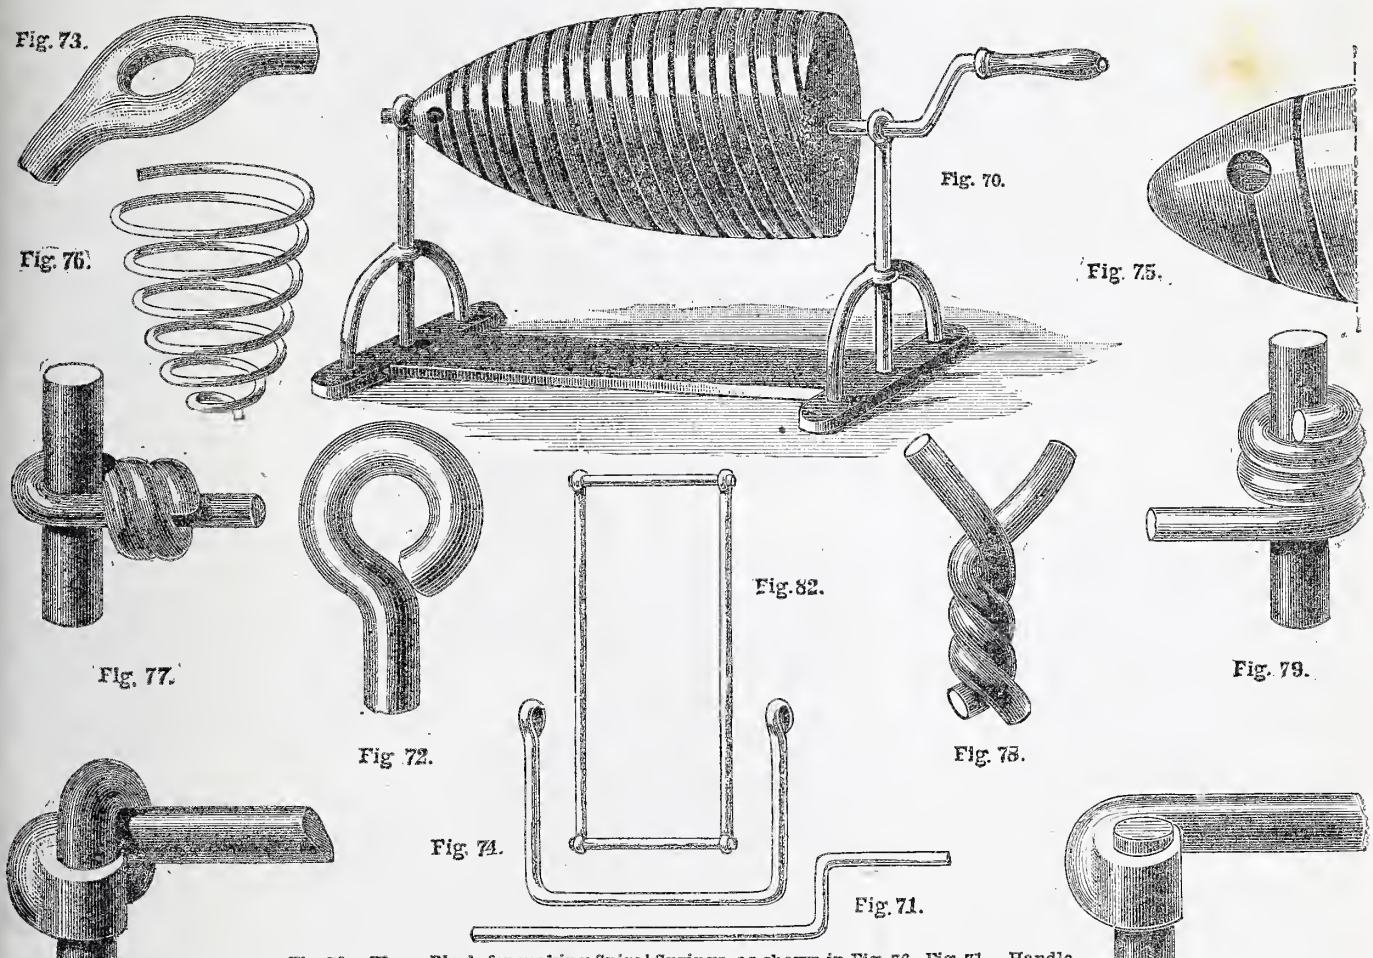

Fig. 70.—Worm Block for making Spiral Springs, as shown in Fig. 76. Fig. 71.—Handle-Bar for Worm Block. Fig. 72.—Top of Perpendicular Rods which support Worm Block. Fig. 73.—Top of Curved Irons which help to support Worm Block. Fig. 74.—Alternative Form of Block Support for use in connection with Vice. Fig. 75.—Enlarged View of Nozzle of Worm Block, showing Catch or Eye. Fig. 76.—Spiral Spring as result of bending Wire round Block. Figs. 77, 78, 79.—Various Methods of Tying. Figs. 80, 81.—Corners of Frames formed by Stout Rods. Fig. 82.—Frame complete as formed by Stout Rods, as shown in Figs. 80, 81.

guided—is entwined around the worm block, and when cut off at the required length and released, a spiral spring is formed.

Supposing that the wire is worked round the block for a third of the latter's length, when cut and released it would be found that it will spring out considerably, thus increasing in width and shortening in length, although it can be turned with the fingers to the proper size again. If it were not for this "springy" conduct on the part of the turned wire, it would be a very troublesome experience for a workman to release it from the block. In Fig. 76 is proportionately represented a spiral spring, similar to what would result with our worm block.

This expression of "tying" can hardly be said to be correct, for what is generally understood to be tying, in connection with such material as string, is the fastening over and under of the parts to be secured. With wire it is different. If a single end of a wire is to be tied, it is turned round and twisted to itself, as in Fig. 77; and when the two ends of a wire, or a pair of separate ones, are to be united, they are twisted around each other, as in Fig. 78. Sometimes, when a thin gauge wire is used, the operation of tying can be accomplished by the aid of the fingers only; but if wire of any stoutness at all is used, it will be found that the pliers will have to be called into requisition. Another method of single-wire tying is that shown in Fig. 81, but, in my belief, it is not nearly so useful as that described in Fig. 77.

Hereafter, when I refer to "frames," I shall suppose that the reader will have acquainted himself with my notes upon them. Fig. 82 shows a frame. The term can be said to mean the skeleton of a job of any description, as, for instance, fire-guards or garden arches. According to the size of the article, so will be regulated the gauge of the rods composing the frame. The corners are made either as in Fig. 80 or Fig. 81. Sometimes the joint (Fig. 81) only is necessary. This is for small work, as the wires, when once turned over within the frame, hold all parts together, and with the additional strength afforded by stay-bars (of which more is said elsewhere) is all that is required; but for large work it is desirable to use the joint shown in Fig. 80.

The term "knuckles" is used in connection with turning over. That part of a wire which encircles a rod of a frame is a knuckle. When it is said that knuckles are inward, the meaning is that the wire is so bent towards the middle of the work as the article will appear when completed; and the same applies, in a reverse manner, when knuckles are said to be outward.

## OUR GUIDE TO GOOD THINGS.

**** *Patentees, manufacturers, and dealers generally are requested to send prospectuses, bills, etc., of their specialities in tools, machinery, and workshop appliances to the Editor of* WORK *for notice in "Our Guide to Good Things." It is desirable that specimens should be sent for examination and testing in all cases when this can be done without inconvenience. Specimens thus received will be returned at the earliest opportunity. It must be understood that everything which is noticed, is noticed on its merits only, and that, as it is in the power of anyone who has a useful article for sale to obtain mention of it in this department of* WORK *without charge, the notices given partake in no way of the nature of advertisements.*

### 59.—JACOB'S IMPROVED WINDOW-BOX.

NATURALLY enough, if one does not exactly like any article or appliance in every-day use, and further happens to be of a constructive and, may I say, alterative condition of mind, one tries to improve on existing circumstances, and to make life in that particular direction more worth living. That this was the case with Mr. Thomas Jacob, Cabinet and Joinery Works, 31, Cleveland Mews, Fitzroy Square, his "Improved Window-Box" clearly shows; and a little reflection will show any reader who understands, and is fond of, gardening, that Mr. Jacob has made life moro worth living for plants that are destined to pass their time, or the greater part of it, in a window-box, and for persons who have perhaps no opportunity of growing plants in any other way, by having made better provision than heretofore for keeping plants in a healthy state. When Mr. Jacob sent me his model for inspection, he wrote: "I took this matter in hand because I always regarded the ordinary window flower-box as an examplo of the most primitive and thoughtless construction to be met with, and although much expense has frequently been lavished upon it by the addition of artistic tiles, it cannot be said that the result is satisfactory. I therefore set myself the problem of producing a flower-box that should he efficient, as regards drainage and ventilation, artistic in form, of greater durability, and at the same time cheap. Ventilation and drainago, tho most important objects,

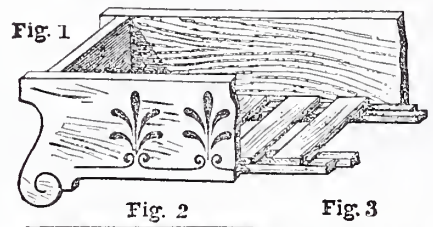

**Fig. 1.—Diagram showing Construction of Box, and open and movable Bottom formed of broad Laths. Fig. 2.—Plan of Box seen from above—A, A, Ledges. Fig. 3.—Plan of Bottom.**

are provided by a trellis bottom, which is raised about 1½ in. This, as a convenience of manufacture, and that it may be renewed if desirable, is loose. Improved form is ohtained by allowing the front of the box to project beyond the ends of box, and shaping it. Inexpensive artistic effect is produced hy a painted decoration, although tiles may be applied, if desired. With regard to the strength of this hox, the improved method of construction ensures that, unless it is really broken to pieces, it will not give way. Such a box, 3 ft. 6 in. long and decorated as model, can now be sold for 10s. 6d." I agree with Mr. Jacob in all he has advanced with regard to his box. The open bottom, which is movable, certainly provides ample means of drainage and means also of aëration or, as he terms it, ventilation. Tho construction of the window-box, as described by Mr. Jacob, is shown in Fig. 1, from which it will be seen that the front and back are nailed to the ends, and that the front, which projects beyond and over the edge of the brick-work forming the side of the window, is shaped. Fig. 2 shows a plan of the box as seen from above, and from this it will be noted that two slips, A, A, about 1 in. square, are nailed to the inner surfaces of the front and back, at a little distance above the lower edge. These ledges receive and sustain the ends of the broad laths of wood which form the bottom, and which are nailed on to two laths running transversely from end to end. The way in which the bottom is made is shown in Fig. 3. The laths need not be so far apart as shown in Fig. 3; it will be sufficient if they are about ½ in. apart and 2 in. in breadth. If the plants are grown in mould placed in the box, a layer of moss or coarse cocoa-nut fibre should be strewn over the laths.

THE EDITOR.

## SUGGESTIONS FOR WORKERS AND HINTS TO INVENTORS.

PAPER MOUSETRAPS.—An American journal, under this heading, tells an amusing story, which may serve as a useful hint to those whose premisos are overrun with mice. It is to the effect that in a house where fly-papers were extensively used on account of a plaguo of flies some were accidentally left on the kitchen floor one night when the family retired to bed. Next morning the mistress was delighted to find that several young mice had been caught by the fly-paper—tho sticky qualities of which happened to be superior—and that, taking the hint, she set a fresh series of papers coated with birdlime, which very shortly caught all tho obnoxious little rodents on the premises. The idea is not a bad one, whether the story be truo or merely invented.

A REAL "BACHELOR'S BUTTON."—Several attempts have been made to provide a button capable of quick and secure attachment to clothes when needle and thread, or someone who knows how to use them, are not at hand. These qualities have been secured by devices in the market; but the button invariably fails in ono important essential. The shank, being of metal, is unyielding, and the consequence is that it is most unpleasant to deal with, there being a difficulty in passing the button through the button-hole. What is wanted is a soft (preferably string) shank which can, at the samo time, be securely fastened to the garment. The inventor of some simple device in this direction would earn the blessings of male humanity and, we venture to think, a substantial return for his trouble.

## SHOP:

### A CORNER FOR THOSE WHO WANT TO TALK IT

**** *In consequence of the great pressure upon the "Shop" columns of* WORK, *contributors are requested to be brief and concise in all future questions and replies.*

*In answering any of the "Questions submitted to Correspondents," or in referring to anything that has appeared in "Shop," writers are requested to refer to the number and page of number of* WORK *in which the subject under consideration appeared, and to give the heading of the paragraph to which reference is made, and the initials and place of residence, or the nom-de-plume, of the writer by whom the question has been asked or to whom a reply has been already given. Answers cannot be given to questions which do not bear on subjects that fairly come within the scope of the Magazine.*

### I.—LETTER FROM A CORRESPONDENT.

**Wire-work Errata.**—J. S. (*London, N.*) writes:—"I am sorry that upon page 293, No. 123, Vol. III., are two errors, one palpably my own. From line 21 it should read . . . . . 'wires A, B, C, D, E, F would be parallel with the free portions. M, N, O, P, Q, R; and those of G, H, I, J, K, L parallel with S, T, U, V, W, X.' On line 36, Fig. 53 should read Fig. 58."

### II.—QUESTIONS ANSWERED BY EDITOR AND STAFF.

**Current for 5 c.-p. Lamp.**—ELECTRO.—A 5 c.-p. Edison-Swan lamp with a voltage of 5 volts will take 3 ampères of current to light it; whilst the same candle power may be obtained from a lamp of higher resistance requiring a voltage of 65 volts, by employing a current of ·35 ampères. If accumulators are to be used, we shall require one cell for each 2 volts of lamp voltage, and one square foot of positive plate surface for each six ampères of current required. Thus, a 5 volt 5 c.-p. lamp to burn ten hours would require an accumulator battery of three cells, each cell having at least five square feet of positive plate surface. It will be better to exceed this by 20 per cent., to prevent undue exhaustion. The plates should be totally immersed in the solution, and the distance between them may be reduced to a minimum ascertainable by practice—care being taken not to short-circuit the plates. The waste will be variable, and can only be ascertained by actual measurement in each instance.—G. E. B.

**Copper-Plating Solution.**—X. E. A. (*Sheffield*).—Your zinc plates may be smoothly coated with copper in an alkaline copper solution worked with a three cell half-gallon Bunsen battery, and an anode of pure sheet copper equal in area to the surface of the sheets to be coated. The alkaline copper solution is made as follows: Dissolve 2 lbs. of copper sulphate in 1 gallon of hot water. When this is cold, stir in enough liquid ammonia to first throw down a precipitate, and then dissolve this to form a beautiful blue solution. Dilute this with

1 gallon of cold rain-water. Next, dissolve 6 lbs. of 85 per cent. cyanide of potassium in 2 gallons of rain-water, and add this to the blue solution. The blue colour will all disappear, and the resulting solution will be of the colour of old ale. Pass this through a calico filter, and allow it to rest for some twelve hours before using.—G. E. B.

**Carpentry.**—R. K. (*Brockley, S.E.*).—Could you teach, or have you a shop you could hold classes in? Could you write effectively on any subject? I am truly sorry to know you are afflicted, though you are not specific on the subject. With the present taste for enamelling, you might make suitable articles in wood, and sell them to fancy shops; or if you can make model ships well, there is a sale for them, or fittings, which, judging by your occupation, you would be likely to understand.—B. A. B.

**Arm Chair.**—ERMIUS.—I must ask you to give me fuller details of the chair you allude to, as I am inclined to think that it is a patented article. You should try to ascertain whether it is patented, and send a rough sketch.—J. S.

**Workshop in Garden.**—PUZZLED.—You cannot erect any permanent structure in your garden, and remove it on giving up the house, without previously coming to an understanding with your landlord, and obtaining his permission to do so, which you should have in writing. See papers entitled "A Tenant's Greenhouse," in Vol. I., pp. 177, 211, and 227 of WORK, otherwise Nos. 12, 14, and 15. This will answer your queries with regard to construction, concrete floor, etc. If you are building a greenhouse you may sink the floor, if you like; but on no account sink the floor of a workshop. Let this be rather above the surface of the ground than below it.

**Whitewashing.**—W. A. (*Shildon*).—Sorry we could not help you in time, for we are well-disposed toward the co-operative movement and its workers, who are strong supporters of WORK, we know. There is no reason why you should not make "good whitewash," and use it properly—providing you allow for practice and experience. First put the water in the pail, then break up the whiting as you put the same into it. After standing, pour off the superfluous water; then add a little lime blue, as a faint grey dries a purer white than whiting alone. It should be quite stiff, not at all sloppy; now add about 4 lbs. of patent size, already melted but not too hot, to the pail two-thirds full with whiting, and thoroughly mix it together with your hand and arm. When cold, it will be set or jellied, and if necessary, may be thinned with a little water for use. Distemper of any kind should never be put over old, dirty stuff, but the latter washed off. A good tradesman will *not* "flap" his brush in working proper distemper; he will make very little noise, using the tip of his brush only. Whitewash or any distemper can be laid off in any direction *from* the outer or working edge. Splashes are the result of "watery" wash, not *jellied* stuff, and want of experience in working. Read the paper on "Distemper" in Vol. I.—F. P.

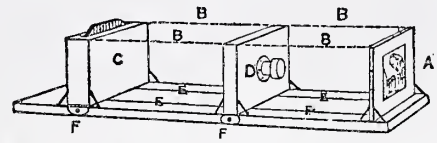
**Die Sinking.**—R. W. (*Bradford*).—There are good practical articles on the subject in the "Encyclopædia Britannica" and other cyclopædias. There are, as far as I know, no books published on the subject.—H. S. G.

**Gassner Dry Battery.**—D. O. W. (*Ipswich*).—Make the ingredients into a paste to the consistency of mortar by adding the concentrated chloride of zinc solution. A capped carbon plate with binding screw embedded in the cap, as employed in the construction of the Leclanché cell, is employed as the negative element. Put a layer of the paste to the thickness of one inch in the zinc cylinder or cell, set the carbon plate in this, and fill all the cylinder around the carbon plate with the paste to within half an inch of the top. Seal with pitch or marine glue.—G. E. B.

**Index to Vol. I.**—D. O. W. (*Ipswich*).—On page 328, Vol. I., you will find the following announcement. "An Index to the First Yearly Volume of WORK has been prepared, and can be obtained by order from all booksellers, price one penny. It is included in the last monthly part of the volume (Part 12)."—G. E. B.

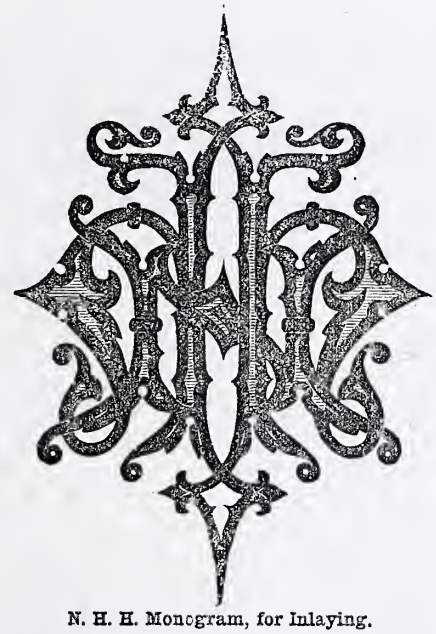
**Bunsen Cell for Silver-Plating.**—AN AMATEUR.—The Bunsen cell may be used for this purpose, but the Daniell is superior, because its electro-motive force is lower. You do not say what kind of soft metal you wish to plate, but it is, presumably, some alloy of lead such as pewter or Britannia metal. The books are right in enforcing absolute cleanliness, especially in plating on such alloys. It is best to clean the article thoroughly, rinse in a potash solution, and transfer direct from this to the plating solution without loss of time or rinsing in water. The battery must be on ready to supply current at once, and so "strike" the silver on the article before the solution has time to act on the metal. If you will follow these directions, and avoid heavy pressure with the burnisher, the silver coat should not strip whilst being burnished. You will not find a better hook than that by A. Watts, so frequently mentioned in Vol. I.—G. E. B.

**Enlarging Camera.**—J. D. (*Hull*).—The space at our disposal in these columns is too limited to permit more than a rough outline of how to make an enlarging camera. It consists mainly of three frames, two of which are movable and slide along in grooves on the surface of a board or table about 5 ft. long. These frames are connected by a light, tight body made of black twill, which is kept extended by means of cords or elastic attached to the corners of the frames. The frame in the front—that intended to hold the transparency or negative to be copied and enlarged—is firmly attached to the base-board. The centre frame is designed to carry a small lens, as a quarter-plate portrait, or 5×4 rapid rectilinear lens. The remaining frame is made to hold the dark slide in which the sensitive plate or paper is placed. The distance between these frames regulates the size of the enlargement; the nearer the lens is to the object to be copied and



**Enlarging Camera—A, Transparency; B, Elastic Cords; C, Dark Slide; D, Lens; E, Guiding Cords; F, Binding Screw.**

enlarged, the larger the enlargement will be, and *vice versâ*. Provision is made for a piece of ground glass to be inserted in the exact position that will be held by the sensitive plate, and on this the image is thrown, the size adjusted, and the definition of the image properly secured. The transparency or negative to be enlarged must be equally illuminated over its whole surface, which is most easily done by aid of a reflecting screen adjusted outside, and at a proper angle. In case of artificial light a condenser is generally made use of, and the photograph to be copied placed close to it. A proper exposure being given, the dark slide is removed, and the plate or paper taken out and developed, *secundum artem*; the mode of development being dependent on the sensitive surface employed, and in no way differs from other photographic development. The means of doing this is described fully in many elementary handbooks on photography. The best way is undoubtedly to see some experienced worker do it. The principal points to be remembered in enlarging are—to let no light fall on the sensitive surface except that passing through the lens; to ascertain that the definition of the image is good; and to give the proper exposure. Above is a diagram of the whole arrangement.—D.



**N. H. H. Monogram, for Inlaying.**

**Monogram for Inlaying.**—FRETWORK.—In reply to FRETWORK, I submit design herewith of the letters "N. H. H." monogramically arranged. When cleanly pierced and carefully inlaid it should prove an elegant yet effective piece of work.—A. C.

**Photographic Studio.**—NEW SUBSCRIBER.—A portable studio is a somewhat indefinite description, as it may be anything from folding canvas and poles to a four-wheel van. *Any* building put together with screws unattached to any fixed foundation is termed portable. There has been no description at present given in WORK of a portable studio. The term indicates a somewhat small arrangement in comparison with the usual brick and glass building, although size has really very little to do with it. A room, say, 25 ft. long, 12 ft. high to ridge, and 10 ft. wide, will make a useful size of a ridge roof pattern. Glazed on one side of the pitch of the roof and one side to within about 4 ft. of each end—which may be opaque—it will afford sufficient facility for taking single portraits or small groups. The frame may be of wood, and the opaque portion constructed of match-boards, covered on the inside with canvas and papered. A door may be made at one end or on the unglazed side for ingress and egress. The floor should be a little above the surface of the ground for dryness' sake, and may be supported on brick or stone piers. Any builder would be able to construct one given these dimensions. If the framing is put together with nuts and screws, the studio will be portable for all intents and purposes. The height of the sides should be about 8 ft.—D.

**Glass-Sign Gilding.**—GILDER.—There is no electrotyping process used for glass-sign gilding and embossing. Continued *practice and experience* with the isinglass method and its accessories will alone, I believe, obtain the perfect results we see on the best glass writing and gilding, such as is turned out by the London firms, brewers' writers, etc. I cannot go here into the detail of the gilding and washing, but, assuming from your letter that these processes are familiar to you, I may help you in the subjoined. What gold do you use? Foreign heat stuff is of no earthly use for glass work, and even with the best English heat, you may not do much better if you use it from the ordinary rouged hooks. The rouge placed between the leaves has much to do with it, and you must get the gold put in books without it, and direct from a genuine heater or trustworthy source. There is a lot of misrepresentation going on with gold-leaf in the trade, especially, I believe, with the quality of foreign heat stuff. English E. D. (ordinary) is worth 1s. 3d. of anybody's money, so don't begrudge a few pence each book for the above kind.—F. P.

**House Painting.**—G. P. (*Elgin*).—In deciding how and in what style a drawing-room should be painted and papered, the matter must be looked at from many different standpoints. First, the cost: how much, roughly, we are desirous to spend on labour and material; secondly, what *aspect* the room has, whether warm or cold—a fact which materially affects, if it does not always govern, the general tone of the colour and scheme; and, thirdly, whether the decorations to be introduced are to be used with the same furniture, hangings, etc., as previously found in the room, or whether the room is to be refurnished, draped and arranged to harmonise with the new decorative treatment. When these matters of expediency are determined, then the purely decorative *ensemble* can be considered. So far as you have given me particulars, I will try to aid you. For S. or S.W. aspects, the prevailing colour—always given by the walls—may be cool tints of any silver-grey, French grey, green-grey, or even so decided as a soft "electric" blue. If the outlook from windows is all green vegetation, don't get too close to decided blue tints; if only "bricks and mortar" in front, decided but "soft" colouring in the room makes it cheerful to sit in. Rooms facing N. or N.E. and thereabouts require warm tints to compensate for the small amount of sunshine and warmth they get. For such, old gold tones, and verging to cinnamon and rich brown, may be best, and from these on to the endless varieties of terra-cotta tints as far as deep crimson. The latter in plain flock paper is excellent for engraving background; whilst in silks it is very popular for walls of State and aristocratic drawing-rooms. With *grey and blue walls*, cream or "ivory white" paint, and panels of door in grey tone with walls is best, ornament on panels "old gold" or grey monochrome, and gilding to mouldings; ceiling cream, grey band of about 9 in. on same next to cornice, ornamental corners and lines of old gold separating the cream and blue. Cornice with cove, or recessed parts, grey, remainder cream, same as the ceiling, with a little "lakey" pink in shadowed parts. For the cornice, painting and flatting is best, but distemper quicker and cheapest. A little gilding on the beads of cornice makes a wonderful improvement; this cannot be done on distemper without other preparation. In your case, have a border about 5 in. deep to match colour of walls, but more enriched, fixed under the cornice, and use a set dado-pattern beneath existing rail, fixing the dado border over the latter. Walnut will suit with blue or golden-brown tones if not too bright. The cover won't hurt, but the modern style is quite opposed to large centre table and set *suites* of chairs, etc. Paint the mantelpiece with the woodwork, and if it is hard and ugly, structurally, you must decorate it a little or drape it, the former if the fireplace is used much. "Workshop Receipts" are published by Messrs. Spon, Charing Cross, London, in four series, at 5s., treating different crafts and sciences. Make sure of the one you want before ordering the volume. Thanks for your letter; most of it has been now answered in other ways. I have, in reply to you, given more than I ought, in order to show any future inquirers that decorative advice cannot be given unless *all* details of the work are sent by the querist, as pointed out.—F. P.

**Loose Pulleys for Circular Saw.**—S. B. (*Nottingham*).—You cannot do better than follow the advice of Mr. Powis Bale on loose pulleys. Certainly he is right in saying that they "should in all cases be bored and rhymered perfectly true." He clearly means that when the pulley rides upon a bush or sleeve, that the bush is to be *fixed* upon the shaft, and the pulley is to revolve on the sleeve (or bush, as you term it). Probably the term *bush* implies a lining to the hole in the pulley, which, I think, would not improve it. Mr. Powis Bale means a covering to the spindle, for he says, in explaining the action of the oil, that motion "causes the oil to

fly immediately to the largest diameter, which is the working or rubbing face of the sleeve." He does not say how the sleeve is to be fixed to the shaft, but no doubt a screw countersunk would do, or perhaps two might be needed. The best plan would be to turn the outside of the sleeve *after* it is fixed on the shaft, and see that the ends are also turned true, and the pulley boss true also on the face, so that when the flanges are fixed they retain the oil, as Mr. Bale says, and keep the pulley in place as well. If any difference in size is made for the purpose of relieving the strain of the belt, I should, by all means, "make the loose pulley with an inclined flange leading up to the fast pulley," and let the difference be small.—B. A. B.

**Polishing Bullocks' Horns.** — ANXIOUS. — ANXIOUS writes to know what acid is used with whiting to finish these with. I expect the acid be saw used was sulphuric acid very much diluted, —say, 1 part acid to 40 parts water; but vinegar answers almost as well. To use whiting and weak acid in polishing horn is of no use unless the horn has been prepared for this final polish by being got smooth by glass or glass-paper or steel scrapers, followed by powdered pumice or powdered Bath brick, this being followed by a still finer polishing powder—viz., rottenstone, which can be mixed with oil. These powders are applied to the work by means of a piece of cloth or felt. The work should be well washed after each stage, so as to remove the coarser polishing powder before applying a finer one. The whiting and acid is used after rottenstone; finally, a portion of dry whiting gives a finishing polish to it, and is best applied by the palm of the hand. One man tells me that a mixture of soapsuds and whiting produces a good surface when it is applied after rottenstone. Plenty of rubbing is necessary in all of the stages.—H. S. G.

**Stopper Bottles for Drugs.**—J. M. R. (*Stratford*).—I believe that chemists usually get their stopper bottles with their drugs from the manufacturing or wholesale druggist. J. M. R. could, doubtless, get his, ready filled with the chemicals he wants, from such a firm as Baron, Harvey & Co., Giltspur Street, London, E.C. Yet, as he asks for the address of a manufacturer, I may mention the York Glass Co., York, who make a special feature of these bottles.—S. W.

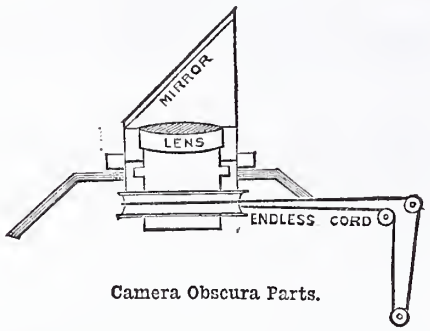
**Tricycle Mechanics.**—R. S. (*Airdrie*).—I have not heard of a tricycle to draw by electricity or air being lately brought out in America. Both steam and electric tricycles have been tried in this country with some measure of success. For common use, no power other than the feet has yet been successfully introduced; steam, I believe, will never be a success. Compound air requires strong heavy vessels to contain it, and the machine would be necessarily heavy. Electric motorology, so to speak, is yet in its infancy, and no one can imagine what it is capable of accomplishing, if men only knew how to construct an apparatus to utilise it to its full extent. As to its application to tricycles, I have no doubt it will yet be largely employed. Meantime, I would advise your correspondent to provide himself with a good tricycle, and have for a motive power his own pedal extremities.—A. S. P.

**Simplex Dynamo.**—F. D. (*Liswalt, N.B.*).—I cannot quite understand how you have wound the armature of your dynamo. You say you have "wound the wire *all on the outside* of the ring.' I suppose, therefore, that you have treated the ring as a drum, and wound the wire over it. Have you divided the ninety yards of wire into three sections and provided a six-part commutator for the ends? If so, are you sure you have made the connections right? If you have not done so the machine will not give any current. Supposing you have wound the wire on all right and connected the coils properly, I do not think you have gained anything by winding such a thin ring as a drum with the wire all on the outside. You have now only thirty-five yards of active and fifty-five yards of dead wire on the armature. I cannot say what you may expect from your machine—probably a current of 3 ampères at a pressure of thirty-five volts when driven at a speed of 1,300 revolutions per minute. Possibly you may get enough to light three 8 c.-p. lamps.—G. E. B.

**Discs for Electric Belt.**—L. W. (*Islington*).—I should advise you to get some thin sheet copper and thin sheet zinc, and cut out some discs the size of half-crown pieces. Coat these with thin flannel and sew them to the belt. I cannot tell you where they may be purchased. If you find any difficulty in getting them, write to my brother at 19, Avenue Road, Lewisham, S.E., and ask him to make some for you. He offers to get any electrical appliances for amateurs.—G. E. B.

**Nickel-Plating.**—FEODO.—You will find the job of nickel-plating a tricycle a most expensive one, as the necessary vats for such large work will cost a lot of money to purchase. Far better get it done by a professional plater. I hope to describe the whole process of nickel-plating in an article on the subject, but have not space at my command for this in "Shop," and a short paragraph on this art will be useless to you. In reply to your questions, I may say that nickel may be deposited from a double sulphate of nickel and ammonia solution direct on to the iron or steel without having to first copper the parts. But they must be first freed from organic impurities contracted in polishing, by boiling them in a solution of caustic potash, then rinsed in a solution of caustic potash, then rinsed in a solution of cyanide of potassium, and transferred at once to the nickel-plating solution before they have time to get rusted. A Bunsen battery of large cells will be needed for large articles.—G. E. B.

**Camera Obscura.** — NEW FANCY. — Make a sufficient number of frames. Cover them with Willesden canvas on the outside, and black lining on the inside; they might be hinged together in pairs. The height should be about 8 ft., and when set up, bolted firmly together. One side should be left open, and overlap thick curtains hung across as a means of ingress and egress. It need not be said the place must be perfectly darkened when in use. The roof must be made, and frames covered in the same manner as the sides, with an aperture left in the top for the lens. The mirror should be about a foot square, placed at an angle of 45° with regard to the lens, and made to revolve by a cord and pulley, after the manner of an ordinary blind. The kind of lens best adapted is a good single achromatic landscape lens, of the proper length of focus



Camera Obscura Parts.

to cast the image on a whitened table placed at a comfortable height for inspection. There is no necessity to have the table concave; a flat surface will answer every purpose if the lens is a good one. An excellent surface is made by pouring a mixture of plaster of Paris in water just thin enough to pour on to a flat table to about three-quarters of an inch, and let it set properly levelled. A rub with fine glass-paper will at any time renew the surface, and keep it in good condition for inspection. The accompanying diagram will show how the mirror is revolved. The mirror is mounted in a box which revolves, carrying the mirror with it. The sides are filled in with wood blackened, only the front facing the mirror left open, which may be closed when not in use by a shutter. It is as well to arrange it so that the lens can be removed for polishing when required. The whole thing is exceedingly simple. The size of the room is immaterial, so long as there is sufficient space to move comfortably round the table. The whole may be secured with guy-ropes like an ordinary tent, as the positions generally chosen for setting them up are elevated and exposed, and ropes offer the best security. If the building is of hoards, the uprights will, of course, be sunk in the ground, and require no further precautions.—D.

**Electric Time Alarum.**—N. H. Y. (*Battersea*).—Thanks for your letter describing your electric alarum. It does not present any new features of improvement on those already described. A short time since I saw a much more simple method of using an ordinary alarum. The workman connected one wire to a piece of thick brass, and laid it down on the bottom of his clock. He then connected the other wire to another thick piece of sheet brass, and set this with one end resting against the hammer of the bell alarum. When the alarum went off, this piece of brass fell down to the bottom of the clock, and closed the circuit of an electric bell placed near the head of his bed. Thus he had the benefit of two alarums, and did not remove the bell as you have done. Placing the battery in a cupboard by the fireplace is bad for the battery. It should be kept in a cool and slightly damp place.—G. E. B.

**Winding Dynamo.**—H. E. A. (*Hackney*).—The field magnets of your dynamo are of the Siemens type. On such a small machine, having an armature 3 in. long by 1¼ in. in diameter, you will only be able to get 4 oz. of wire, even if it is silk-covered. The utmost current you will get from such a small quantity of wire, without injuriously heating the coils, will be 1 ampère. The smallest wire that will safely carry this current will be No. 22 B.W.G. Four ounces of No. 22 wire will measure 30 yards, and we shall have to reckon one-third of this as dead and useless, because it will work out of the magnetic field on the armature ends. This will give 20 yards of active wire on the armature, and will develop an E.M.F. of 20 volts when driven at a speed of 1,200 feet per minute. To balance this, you will require 1½ lbs. of cotton-covered No. 22 wire in the fields, connected in shunt with the armature coil. Use single cotton-covered wire, well soaked in hot paraffin wax. As an insulating covering for the iron, employ tough brown paper soaked in hot paraffin. Cut strips from this, and soak in hot water to soften them. Dress the iron with hot, thin glue, then mould the softened and prepared paper to the shape of the iron. Allow this to dry and get firm before winding on the wire. You will only need one layer of this if you are careful, in winding the wire, not to cut through the layer. The finished machine will look well if painted with Aspinall's enamel. You may make up a paint for the purpose by mixing Venetian red with methylated spirits, and then stirring in enough white hard varnish to bring the paint to the required consistency. If you get Bottone's book on "The Dynamo: How Made and Used" (latest edition), you will find a whole chapter devoted to winding dynamo machines.—G. E. B.

**To make Cotton Waterproof.**—G. D. (*Woolwich*).—To do this without making it sticky, it must be dried at about 150° Fahr. by artificial heat. The sun on a hot day will do. Get as much boiled oil as is necessary, and mix enough lamp-black to blacken it, if for black work; if for yellow, use ground yellow ochre instead. Then lay the fabric on a smooth surface, and put the oil on with a brush—a shoe brush is best. Let the first coat get quite dry before putting on another. A little patent driers will make it dry quicker—say, ½ lb. to a gallon of oil. If the last coat remains sticky after it is dry, take 1 lb. of shellac to 2 quarts of water, simmer it gently, and when near boiling add a little liquid ammonia to dissolve the shellac: when this is cold mix a little lamp-black for black; if yellow, use it as it is. If the fabric is coated over with this, it will make it hard: put it on with a sponge. Lay the oil on as thin as possible, or it will not dry. Of course, this paint will, in a measure, obstruct the light.—L. Y.

**Tarpaulin.**—CARDIFF NO. 1.—The reply to the query sent is given in WORK, No. 118, p. 222, Vol. III., in answer to the inquiry of an earlier correspondent.

**Bookcase.**—J. P. (*Blackburn*).—The Editor has a paper in hand on the construction of a bookcase. It will appear as soon as practicable, and will, no doubt, help you, though it is intended to be made to stand on the floor, and not on a shelf. By the way, your inquiry about a bookcase of *ordinary* size is very vague, and conveys little or no meaning. Do you not think it would have been nearly as easy for you to have given an idea in feet and inches?—D. D.

**Elastic Mould.**—CICERO.—The following recipe has been recommended:—Gelatine 1 lb., beeswax ½ oz., to which add three-quarters of a pint of water. Boil in a glue-pot to a thick syrup, and pour it over the work to be moulded whilst warm, but not boiling. None but the best and purest sheet gelatine ought to be used.—M. M.

**Removal of Hair by Electrolysis.**—J. S. (*Preston*).—For the removal of hair by electrolysis you will require a bichromate or chromic acid battery of several small cells, and a switch to throw a variable number of cells in the circuit at will. You will also require a pair of platinum or gold needles with suitable handles, costing about 6s. per pair. The needles are inserted in the skin at the roots of the hair, and a current of electricity is passed until the root-glands are destroyed by electrolysis. It may be necessary to employ a large number of cells, some ten or more in series. I do not advise you to perform this operation yourself, as it would be more costly and uncertain in results than when performed by a qualified practitioner. The battery and needles may be obtained from Mr. K. Schall, 55, Wigmore Street, London, W., or Messrs. T. Gent & Co., Braunstone Gate, Leicester.—G. E. B.

**Electric Bells.** — NEW READER. — The book, "Electric Bells: and All about Them," was written by Mr. S. Bottone, Wallington, Surrey, and is published by Messrs. Whittaker & Co., 2, White Hart Street, Paternoster Square, London, E.C. The price is 3s., and it can be obtained direct from the author or publishers at this price by post. Questions cannot be answered in "the next issue" of WORK.—G. E. B.

**Angle Cog Wheels.** — C. H. (*Finsbury*). — I should advise you to write to Messrs. Ormerod, Grierson & Co. (Limited), St. George's Ironworks, Manchester.—F. C.

**Distemper Colours.** — B. A. (*No Address*).—"Recipes for mixing the most fashionable distemper colours for walls for a public institution." This request, simple and plain although it may appear, is really very indefinite. A chapel, a theatre, and a free library would each and all, I presume, come under such a category; but how different are the sentiments associated with each! I, therefore, cannot help you with instructions particular to your special apartment or hall. A few considerations, however, of the subject generally will probably aid you and many other readers of WORK, with whom the handling of mass colours and tints is a most obtuse and difficult problem. The relationship of fashion to colours, rational as it *may* be in connection with bonnets and dresses—*irrational* it most often is—when looked at from any commonsense standpoint, can be but of a suppositionary nature in the practical colour-decoration of apartments. Therefore, we will substitute "useful" for "fashionable," and come to some conclusions. Distemper, or any absorbent *tempera* paint, is certainly preferable to oil paint for public buildings. The former holds the condensed moisture, and then dries out again; whilst with the latter, the moisture gathers on its surface and trickles down the walls. The range of colour suitable for such places is rather limited, unless the scheme of decoration is elaborate, and the colours properly balanced and juxtaposed. In dealing with *masses* of plain tints, mixtures of *pure* pigments, such as red, blue, or green, with *white alone*, are seldom successful. The larger the mass presented to the eye, the less must be the strength of *colour*. Now, every positive

colour effect conveys a definite sensation; whether we can analyse it or not, such is the case, unless the beholder is colour blind to more or less extent. The sensation of red is chiefly warmth; of blue, coolness; of yellow, brilliancy and excitement; and, lastly, of green, a cool and soothing effect upon the mind, usually, as well as in scientific reality to the colour-nerves of the human vision. Without going further into theory here, you can now apply the above to your own purpose. Turn to the new tint circular of the Alabastine Company. Do you want a warm-looking room, use No. 6 or No. 18; or if extreme warm richness is wanted, dull tones of No. 24. For cool, well-lighted halls, etc., No. 16 is very soft and suitable, and lights up admirably. Nos. 9 or 23 are also good, but rather too bright if the light is strong. No. 1 is a good serviceable tint, cool and clean, and would not clash with any accidental colour (dresses, etc.) that might be introduced, as in a ballroom. Amber and cinnamon colours are very popular for theatres, contrasted by a little of such as No. 9, but they require clever handling, and are best only used for places lighted by yellow gaslight. Recipes, used in the sense of exact written parts and proportions, cannot be given for *colour* mixing. Experience for ordinary purposes, and added thereto a natural and cultivated faculty for extraordinary instances, can alone be the guide to success. If you haven't got the colour card alluded to, write to the Company at 127, Pomeroy Street, London, S.E. A bed-sitting room would look well in No. 6, with a soft terra-cotta brown (*not purple*-brown, please!) dado for a northern aspect. For a sunny room, either No. 1, 8, 9, or 16, with a dado of 10, 19, 18, or such like, of dull, yellow-brown tones. A stencil border, and, perhaps, frieze stencil of a *darker* tone of dado colour used upon the filling colour, would make a very pleasing finish.—LONDON DECORATOR.

**Medical Coil.**—W. A. S. H. E. (*Sheffield*).—The ordinary Leclanchè cells as used for bells will serve very well indeed for a medical battery, or to form a battery for working a medical coil. They are quite equal in power and efficiency to the special forms of this battery. A special price is charged for the special forms, because special attention is paid to sealing the cells, adapting their form to the box in which the battery is held, and making it portable. Where special portability is desired, I should recommend a battery of dry cells, such as the Gassner, Gent's "Perfect Dry Cell," or the "W. & R" cells, obtainable from Messrs. Gent & Co. Faraday Works, Leicester; or Mr. K. Schall, 55, Wigmore Street, London, W. I do not know the "Harness" cells, so cannot say whether they will work a medical coil successfully or not.—G. E. B.

**Colourless Varnish.**—A. M. (*Liverpool*).—I have a practical acquaintance with both gilding and photography, and yet know nothing of "a colourless varnish used after gilding picture-frames, and which same varnish photographers use for finishing." *Finishing* what? Gilders use, or should use, a final coating of clear parchment size—made from parchment trimmings and water simmered for many hours in a clean saucepan—upon all gold-leaf gilding. Photographers use—or should use; the amateur doesn't always—a coating of a spirit *negative varnish* for finishing his negatives. Cheap frames are "gilded" with white metal, and then coated with a yellow spirit lacquer. For cleaning oil paintings of value and without risk, get Brodie & Middleton's (Long Acre, London) "Anadeiktine," sample bottle, 1s., with instructions. Several good recipes for gold lacquers for brasswork are given in Vol. II. (see Index). I cannot help you more without the exact particulars of your work and wants. A colourless varnish, useful for gold, bronzes, etc., is a solution of white stick lac in methylated spirit.—F. P.

**Whole-Plate Camera.**—F. W. B. (*Leicester*).—If you will refer back to the first volume of WORK, you will see a full and explicit description of how to make a camera whole-plate size. It is very easy to alter the dimensions to 6½ in. by 4¾ in.—the size you require. Of course, rather lighter woodwork may be used, and when panelling is directed, merely clamping will give sufficient strength. Keeping to the general design, many little alterations will suggest themselves to the maker to reduce the labour, and yet afford sufficient rigidity. As to cost, much depends as to the market you go for the raw material; ten or fifteen shillings would probably procure it.—D.

**Self-Acting Fountain.**—W. C. (*No Address*).—An article describing the construction of a self-acting fountain appeared in No. 69 of WORK. From the diagram therein, illustrating the working of the apparatus, you should be able to make such alteration as would suit your purpose in fitting it to an aquarium. The latter is a somewhat difficult job, and I do not recommend a self-acting fountain for the purpose; the oxide from the zinc kills the gold fish, and the dirt, etc., inseparable from a flourishing aquarium, is continually stopping up the jet-hole. It is far better to connect to a water supply and run off to waste.—C. M. W.

**Tray for Coins.**—R. E. D. (*Holborn Circus*).—Your most ready way will be to cut a piece of millboard to fit your wooden tray, and to pierce the holes through this; no levelling of the bottoms of holes will then be required. The millboard can be fixed down to the wood with four, six, or more brass tacks, as size may require. A great advantage of this plan is that, when the acquisition of more coins renders (as it is sure to do) a rearrangement of the collection imperative, the millboard can easily be detached, and a new one cut and fitted in. The holes are most readily cut with gouges of suitable sizes, but in the absence of such tools a sharp penknife will answer the purpose.—M. M.

**Sign Writing—the Lemon Tree.**—GUGLIELMUS.—As I remember (I have lived in a lemon growing country), there is no appreciable difference in foliage between this and the orange tree, but the lemon is less bushy in growth; the fruit, of course, is widely different in form and colour. The annexed sketches, though drawn from memory, will, I trust, be sufficiently accurate for any but scientific purposes. Fig. 2 shows the growth, Fig. 1 is the tree conventionalised to fill the required space. For the purpose in view, GUGLIELMUS is advised to make his fruit big enough, and to give to trunk, fruit, and leaf, a bold black outline. The fruit, to make an effective

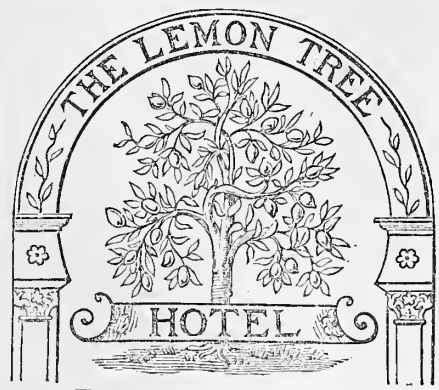


Fig. 1.—Sign of the Lemon Tree.

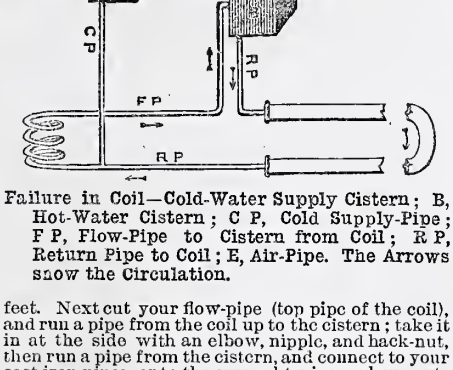
Fig. 2.—Lemon Tree Bough.

sign, should be gilded, and can be shaded up with wash-black mixed with just a dash of verdigris and Prussian blue. The leaves should be of a dark green, something like that of the laurel. GUGLIELMUS will see that the Moorish arch, as sketched, will compare better—will be better filled by the tree—than the Roman one which he suggests. It will also be more appropriate, as being the arch of the countries where lemon trees grow.—S. W.

**Failure in Coil.**—J. L. (*Upton*).—The cause of your coil not circulating properly is because the coil is not low enough. You should have arranged it so that your *lowest* pipe—technically known as the "return"—was slightly above the top of the coil or boiler. As you have got it all fixed, it would be, no doubt, awkward to lower the coil, but you will have to do it or adopt the following plan, which you will find will make it work satisfactorily. Procure a small cistern, which must have a man-hole cover, and also an air-pipe out of the top; fix the cistern a foot or two above your pipes (see sketch), and let the air-pipe run above the supply cistern three or four



Failure in Coil—Cold-Water Supply Cistern; B, Hot-Water Cistern; C P, Cold Supply-Pipe; F P, Flow-Pipe to Cistern from Coil; R P, Return Pipe to Coil; E, Air-Pipe. The Arrows show the Circulation.

feet. Next cut your flow-pipe (top pipe of the coil), and run a pipe from the coil up to the cistern; take it in at the side with an elbow, nipple, and back-nut, then run a pipe from the cistern, and connect to your cast-iron pipes, or to the wrought pipes where cut; this you will see is making the cast pipes wholly a return to the boiler or coil, and you will find it act perfectly. Of course, you have your cold supply taken into the lowest pipe of the coil. I shall be glad to hear how you get on with it, and to help you further if you find any difficulty, but do not think you will.—R. A.

**Preserving Skins of Moles, etc.**—W. F. (*Salisbury Square*).—The dampness of the skins in wet weather of which you complain is probably owing to the use of salt in preserving. The dressings recommended in curing skins are legion, and common salt, bay salt, and saltpetre enter into the composition of many of them. Alum alone will, however, suffice, though the addition of a little corrosive sublimate will render the skin safer from insects. One way is to dissolve the alum, etc., in water, and rub the solution into the skin (on the flesh side) daily for a week or two. Of course, all flesh, fat, etc., should first be scraped off, and it is well to stretch and tack the skin, fur downwards, on a board. Some, however, prefer to use the dressing dry, and instead of stretching to lay two skins flesh sides together after dressing, to roll them tightly up, and tie them. Skins may afterwards be made soft by rubbing over a metal edge.—S. W.

**Dulcimer.**—H. B. (*Wakefield*).—The stringing of the dulcimer is a very simple matter. The lowest note is composed of four brass strings, the next of four steel, the next of four brass, and so on, alternately, to the top of the instrument. If you have been trying to pull the brass strings up to the same pitch as the steel ones it would account for the breakages; but if the instrument has been properly strung, then the fault lies in the wire, as good wire ought to and will go up two or three notes above the pitch at which it will be required to stand. Are you sure you have obtained the right sizes? The dimensions you give of your instrument are out of proportion; one of twenty inches in length on the sound-board would require to be at least fourteen inches deep.—R. F.

**Polishing Ebony Walking Stick.**—E. W. (*Islington, N.*).—Being made of ebony, which is of a very close grain, no "filling" need be used. To polish it, you will require a little white or transparent polish, which is applied with a polish rubber. For particulars of how to make, see No. 108 of WORK, issue of April 11th; and "How to French Polish" in No. 105, March 21st. If the ebony is not perfectly black, you will require a little gas-black or Frankfort black on the face of the rubber; at least, this is the way most polishers would do it. But as you appear to have no knowledge of French polishing, and may have to buy your polish ready made—which I strongly advise—you might do worse than send to Mr. Flack, Steam Works, 75, Blackman Street, London, S.E., for a small quantity of "Ebonite" French polish and spirit varnish; or to Thos. Jackson & Son, 199, Borough High Street, London, S.E., for their "Improved Ebony Polish." No previous staining is required for these, and I believe full particulars of how to apply are given with each bottle. The handle can be fixed on with a little of Prout's bicycle cement, or a little ordinary shellac will do, applied with a hot iron in the same way as the cement.—LIFEBOAT.

**Window-Sash Making.**—I. H. (*Holloway*).—I know of no book specially devoted to sash making. You will find a great deal of information has been given from time to time in WORK, in pp. 177, 211, 364, of Vol. I., and in pp. 192 and 405 of Vol. II. If after reading these you are still in a fix, I shall be pleased to give you any information you may require on receipt of detailed descriptions of what you find any way puzzling, which descriptions you will be very much more able to give after thoroughly digesting the various tips contained in the above numbers of WORK.—E. D.

**Supply of WORK.**—R. H. (*Notting Hill, W.*).—If you or any other reader should experience a difficulty in getting WORK, whether in current or back numbers, you should apply to the publishers, Messrs. Cassell & Co., Limited, Ludgate Hill, London, E.C., and it might be well to quote the name and address of your bookseller.

**Lettering.**—W. P. (*Southampton*).—The letters are done with gold-leaf on an ordinary black ground, and then varnished.—T. W.

**Polish Reviver.**—J. P. (*St. Helens*).—Read carefully replies already given in "Shop" during the last few weeks—"Polish Reviver," p. 238; "Cracked and Dull Polish" and "Polish Reviver," p. 315. These fully answer your question.—LIFEBOAT.

**Bent Shafts.**—T. S. (*Pendleton*).—I cannot advise you to try and bend your shafts for your proposed mail cart, as the process would be too tedious. We have several times bent shafts for light traps: but the cost in time and trouble, to say nothing of the expense of a shaft occasionally snapping in two pieces, far exceeded the price of what we could have bought new bent shafts for. I should advise you to get two shafts sawn out of straight-grained ash free from knots, 1½ in. square when planed up, and 53 in. long. I see from your address that you live near Manchester; therefore I advise you to take your straight shafts to be bent at Thurman's, bent timber merchant, Hulme Street, off Oxford Street, Manchester, where they will soon bend according to any shape you like—indeed, I am not sure but what you can buy them ready bent. However, I would, if I were you, pay them a visit to ascertain before going on any further. When you have got the shafts bent, you just simply round the handles off, and take the average off the sharp edge of the shafts.—W. P.

**Tram-Line Curves.**—J. G. B. (*Oldham*).—The gauge or width between the rails is 4 ft. 8½ in. on most lines, though there are some narrow gauges in use. To get the curve for any particular turning, you must have a plan of the streets, and mark down the largest radius you can get in. This, however, will not affect your invention I take to refer to operating the points. There is no difficulty in the matter. If you send a sketch, I shall be happy to give you an opinion and advice upon it.—F. C.

**Shock Coils and Time Alarum.**—J. K. (*Manchester*).—I share in your pleasure, because you have been good enough to give me an account of your success in making the electric time alarum. It gives me pleasure to know that you—only a youth of fifteen years—have succeeded in making an excellent time alarum at a cost of 5s. The delay in answering your former question was unavoidable, owing to the crowded condition of our "Shop." If we devoted the whole of our little penny worth to the publication of contributions to "Shop," it would take several weeks to catch up with arrears of replies to correspondents. I cannot promise a date for the publication of the articles on shocking coils. You will find Dyer's work on coils a fairly good one for a beginner. Coil making is quite within the province of an amateur.—G. E. B.

**Silvering Carriage Fittings.**—COACH TRIMMER (*Edinburgh*).—Carriage fittings are coated with silver by the electro process. This will be described in due time, when room can be found for the articles. There are no addresses of coach-makers' furnishers in the London Directory; but coach furniture is made and supplied by Mr. C. Bunn, Herbert Street, West Bromwich, and Messrs. J. H. Hawkins & Co., 16, Station Road, Walsall. Of coach platers there are twenty mentioned in the directory, amongst which may be noticed Messrs. J. H. Radcliffe & Co., 8, Barrett Street, Manchester Square, London, W., and Messrs. Smith Brothers, 53, Paul Street, Finsbury, E.C.—G. E. B.

**Imitation Marble.**—E. M. H. (*Glasgow*).—The reply on p. 112, No. 59, to similar query will suit your frecstone stand equally well, taken in conjunction with the following: As the surface of stone will not be so smooth and regular as wood, I would advise you to rub up a stiff paste from warm patent size and finest whiting. After the first coat of paint is thoroughly hard, scrape on or brush on, according to convenience of surface, a good coating of this "filling up." When same is quite dry, rub it down to a smooth and level surface with fine glass-paper. A coat of linseed oil, with a little patent driers only added, is next given; this hardens the surface. When dry, proceed with the painting as described on p. 112.—F. P.

**Picture-Frame Gilding.**—S. S. S. (*New Kent Road*).—The writer, who humbly but firmly claims to be a "real practical man," might have practically helped you had you stated the *nature* and *condition* of the frames to be gilded. I must refer you to pp. 603 and 795, Vol. I., as answers thereto appear worth your careful perusal. If you mean how frames *water-gilded*—viz., in mat and burnish size—are properly re-gilded *same* way, it is a matter beyond "Shop" entirely. The labour necessary to thoroughly "re-get-up" a water-gilt frame is so excessive as to make it seldom done, and they are usually re-gilded with *oil-gold* size. Although the process may eventually be thoroughly explored in WORK, few would benefit therefrom. If you want to learn it thoroughly from a professed "carver and gilder," advertise for lessons.—F. P.

**Varnish.**—G. H. (*Wakefield*).—Oil varnish, if at all exposed to the air, will thicken and become "fat," owing to the mixture taking up oxygen; the cheap qualities, by reason of the copal gum being substituted by common resins, become so affected much quicker than good "copal." They can never regain their original qualities by any dilution or addition, but may sometimes be so thinned with turpentine as to be useful on common work. The "turps" re-dissolves the oil and resin, but, of course, reduces the bulk and gloss. Mathieson Brothers, of Ardrossan, N.B., make an "enamel oil" which can be advantageously mixed with varnish. To add ordinary linseed oil means that the varnish will never properly dry.—F. P.

**Paper-Hanging.**—C. H. (*London, S.E.*).—It seems somewhat difficult to describe any method of "folding a pasted length of paper in order to convey it from the board to the wall" as being "the *correct* one," since individual experience and expertness is the only standard of judgment we have. One of the best that a professional worker will use for lengths of about 8 ft. I will endeavour to explain. The lengths being cut to about the right size and properly arranged for clean pasting upon the pasteboard, the lower half is first pasted, and then folded over for about 18 in. or more of doubled length. The paper is moved along and pasted complete; the upper half is then folded over for a distance, and then the top edge turned right back. In conveying and fixing it, the top edge is taken hold of firmly but carefully by finger and thumb of each hand, and the fold is held by the other fingers. Assuming a practised and smart man is working, he will then mount the steps in a convenient position without holding with his hands, but using them both for the paper. The worker being in position, he drops the top fold, which has been held by his fingers, and fixes the upper half in place. If correct in plumb, this is rolled or brushed; and then, descending to the ground, the bottom end is unfolded, and the length brushed down, trimmed, and completed. If the man is working from a plank and scaffold, he must, of course, use one hand to get up to his work, in which case the top is folded as the bottom, and the length thrown over one arm. The difference between having the top edge in the fingers ready for matching and that of having to unfold the same, makes a great difference in the speed of paper-hanging. I hope this is the answer you wish for, and that I have made myself clear. If you use this method I don't think you can better it.—F. P.

## III.—QUESTIONS SUBMITTED TO CORRESPONDENTS.

**Opal Glass-Letter Cutting.**—OUVRIER writes:—"I should be glad to have the address of makers of the appliances for cutting out glass letters, and any information respecting the method of making same."

**Heliograph.**—R. N. (*Grays*) writes:—"Can any of your readers describe how to make a heliograph, and also the mode of signalling with it?"

**White Letters on Glass.**—GLAZIER writes:—"Can anyone tell me how to remove the same without breaking?"

**Pumps.**—J. H. (*No Address*) writes:—"Will any reader kindly inform me where I can get a hook about pumps, engines, and such like matters? I want something with drawings, so that I can see the inside steam passages."

**Refrigerator.**—J. H. (*Liverpool*) writes:—"I have a refrigerator to make. Would any reader give me a plan of one fit for a butcher's shop?"

**Bones.**—E. F. P. (*Warrington*) wishes to know if any reader can tell him of any hook or hooks on "Bones," or the uses, etc., to which bones are put.

**Rubber Arrow Shooter.**—ARROW SHOOTER will be obliged to any reader who will tell him how to make a rubber arrow shooter.

**Hat Making.**—J. S. G. (*Portsea*) writes:—"Can any correspondent give me a little assistance in hatting? Being a hatter's salesman, I should like to know the process of half-blocking a silk hat; also, whether there is any way of taking grease or other marks out of hats other than washing the hat, for I find it takes such a long time to dry a hat when washed; and I often have a customer that wants his hat cleaned and ironed whilst waiting."

**Terra-Cotta Plaques.**—PLAQUE ARTIST writes: "Where can I purchase, good and reasonably, terra-cotta plaques of various sizes—not a large quantity, but a few dozen or so at a time."

## IV.—QUESTIONS ANSWERED BY CORRESPONDENTS.

**Root's Blower or Blast Fan.**—M. (*Bishop Auckland*) writes, in reply to F. W. B. (*Huddersfield*) (see page 286, No. 122):—"Try A. Walton, 9, Queen Anne Street, Stoke-on-Trent, for castiugs of small blast fan."

**Saw.**—CHOPSTICK writes, in reply to CONSTANT READER (see No. 120, page 251):—"The sketch and information you ask for would take up too much space in 'Shop' columns. I will, therefore, send a brief article on the subject shortly, which will give you full information; but I can tell you this now: you must not expect to cut 3 in. stuff without some hard work with only one man on the wheel—it is best to have two when there is any quantity to do."

**Upholstery.**—E. W. C. (*Leicester*) writes, in reply to T. C. (*Belfast*) (see page 286, No. 122):—"Your question is unintelligible. Do you mean an outside cover to cover the whole of the article of furniture, or do you mean hair seating, otherwise known as hair cloth? Also, what do you intend to cover, either scroll, back, or seat, and is it a sofa or couch? The former has a scroll at both ends, and the back extends between the two; the latter has only one scroll, and the back only extends about three-quarters of the seat. If you will state definitely what you intend to cover, also with what material, I will try to help you."

**Worm and Wheel.**—E. G. PLATT, Birbeck Works, Birbeck Road, Ridley Road, Kingsland, N.E., writes:—"I see by one of your answers in 'Shop' (see page 269, No. 121) that you cannot give your correspondent an address of rack and wheel, or worm and wheel maker. I beg to offer myself as same."

**Battery.**—THE ELECTRICAL COMPANY (*Crewkerne*) write, in answer to T. R. (*Ashton-le-Willows*) (see page 270, Vol. III.):—"Our new central zinc batteries would answer the purpose required. The prices are—No. 1, 1s. 9d.; No. 2, 2s.; No. 3, 3s."

**Air Cushion.**—H. H. P. writes, in reply to H. R. (*Clapham*) (see page 222, No. 118):—"If H. R. will fill the cushion with air, then put it in a tub of water and press it, he will find where the leak is by the bubbles that arise."

**Bread Machines.**—W. A. (*Faversham*) writes, in reply to JEAN (see page 286, No. 122):—"You could not do better than apply to Mr. W. F. Mason, engineer and patentee, Longsight, Manchester, for prices and particulars. His machines are simple in construction, and make a good, even, and smooth dough. They are also fitted with friction gear for throwing dough out, which I must say saves a lot of winding tank up and down, as in most machines. The bakehouse where I am has been fitted up by Mr. W. F. Mason, and I cannot speak too highly of the way I find things to hand, which is a great pleasure in the trade."

## V.—BRIEF ACKNOWLEDGMENTS.

Questions have been received from the following correspondents, and answers only await space in SHOP, upon which there is great pressure:—G. H. (*St. Helens*); C. S. (*Leigh*); E. G. (*No Address*); T. B. D. (*Glasgow*); W. H. C. (*Leicester*); F. W. (*Kentish Town*); F. H. (*Battersea*); P. McN. (*Shettleston*); R. A. B. & Co. (*London, W.*); B. A. C. (*Glasgow*); L. & Co; F. M. (*Portsea*); W. C. S. (*Edmonton*); W. J. (*London, N.E.*); W. T. (*London, N.*); W. K. (*No Address*); M. A. P. (*No Address*); INCUBATOR; E. A. P. (*Beckenham*); C. S. (*Leominster*); H. J. C. (*London, S.E.*); J. W. (*Wellington, Salop*); W. H. F. (*Kingston*); J. O. H. (*Wandsworth Common*); B. A. B. (*Hampstead*); G. E. L. (*Battersea*); W. J. A. (*St. Helens*); DEVON; T. L. (*Peckham*); F. W. B. (*Sunderland*); W. J. D. (*Manchester*); J. E. B. (*Chesterton*); W. S. (*Pontefract*); M. P. D. (*Brighton*); W. W. (*Bristol*); F. H. (*Hull*).

## The Story of the Heavens.

By SIR ROBERT STAWELL BALL,
LL.D., F.R.A.S., Royal Astronomer of Ireland.

*With Numerous Illustrations and Coloured Plates.*

*** **With Part 1 will be given a large and valuable STAR MAP, indicating clearly the various Constellations in such a manner that they can be easily recognised by the observer.**

SO considerable has been the progress of Astronomy during recent years, that in responding to the demand which has arisen for a NEW SERIAL EDITION of The Story of the Heavens, the Publishers have arranged for a very complete revision of the work.

Sir ROBERT BALL has made valuable additions to the book, and has incorporated in it the **latest results of astronomical research,** whilst in order that the New Edition may be perfect in all respects it has been re-set throughout in **New Type.**

"It is doubtful whether any previous effort to popularise astronomy, in our language at any rate, deserves to rank as highly as *the delightful and most instructive volume* which the Royal Astronomer for Ireland happily entitles THE STORY OF THE HEAVENS. *Sir Robert Ball not only astounds the imagination, but convinces the reason of his readers.*"—SCOTSMAN.

CASSELL & COMPANY, LIMITED, *Ludgate Hill, London.*

*The New Fine Art Work.*

Messrs. CASSELL & COMPANY will publish in **Monthly Parts,** price **7d.,**

## Historic Houses of the United Kingdom.

**PROFUSELY ILLUSTRATED.**

***PART 1 ready SEPT. 24, price 7d.***

This New Work will present a delineation by pen and pencil of the principal ancestral homes of Great Britain and Ireland, which are so closely connected with the chief events that have marked the course of our national history. As in the case of "CATHEDRALS, ABBEYS, AND CHURCHES," the text will be furnished by well-known writers, whose descriptive accounts of the various "Houses" will be full of interesting facts, and lightened by anecdotal reminiscences of illustrious persons, past and present. **"Historic Houses"** will be profusely and appropriately illustrated with high-class Engravings, and the fine-art character of the Work will be preserved in all branches of its production.

*** *Prospectuses may be obtained at all Booksellers', or will be sent post free on application to*

CASSELL & COMPANY, LIMITED, *Ludgate Hill, London.*

# AMATEUR PHOTOGRAPHY.

*AN EXCELLENT OPPORTUNITY FOR BEGINNERS.*

In making their Cheap Photographic Sets for Boys, and Beginners whose means are limited, J. H. SKINNER & CO. have striven to reach the **maximum of efficiency, combined with the minimum of cost.** This they claim to have now attained by using the best machinery wherever practicable, and by selling them at a small profit they are able to place in the market their **Improved Eclipse Cameras and Outfits,** which for quality and price combined defy successful competition. Every set guaranteed perfect, and if found otherwise on receipt will be exchanged or money refunded on return of goods.

**THE IMPROVED ECLIPSE CAMERA SET, price 3s. 6d.,**

Consists of a full ¼-plate sliding bellows Camera (taking pictures up to 4¼ in. by 3¼ in.), made of solid mahogany, polished, fitted with a good double convex, brass-mounted lens, improved dark slide, light-proof; focussing-screen, improved focussing arrangement, packet of dry plates, developing and fixing solutions, and full instructions, enabling any amateur to take a good Photograph. Price **3s. 6d.;** or securely packed by Parcels Post, **4s.**

**7s. 6d. COMPLETE PHOTOGRAPHIC OUTFITS. 7s. 6d.**

Comprising ECLIPSE CAMERA SET, as above: also PHOTOGRAPHIC PRINTING APPARATUS, consisting of hardwood printing frame, with brass spring back, sensitised albuminised paper, gold toning solution, fixing solution, glass rods, cards for mounting, with complete instructions. Also hardwood folding tripod stand and focussing cloth. Price **7s. 6d.;** securely packed, post free, **8s. 6d.** If packed in portable wood case, with hinged lid and leather strap, as in Illustration, **9d.** extra. Every set is carefully examined before being sent out, and guaranteed to be in working order. N.B.—If Apparatus does not give satisfaction, and is returned uninjured within three days of receipt, we guarantee to refund purchase-money.

**THE STANLEY OUTFIT, price 10s. 6d.; by Parcels Post, 11s. 6d.**

This set is precisely the same as the 7s. 6d. Outfit, except that it includes a better Camera, with folding tailboard, a double dark slide, and is sent out packed in hardwood box, with hinged lid and leather strap, without extra charge.

**The Marvel, Norfolk, or Compacta ¼-plate Camera Sets,** price **£1 1s.** each; or by Parcels Post, **1s.** extra.

These sets consist of a superior ¼-plate Camera, with hinged focussing screen, will take horizontal or vertical pictures, mahogany double dark slide, superior achromatic lens in sliding brass mount; also polished hardwood folding tripod.

For better sets, see our Photographic Catalogue, price **2d.,** post free.

***A Wholesale Dealer's Stock-in-Trade at about Half-Price.***

J. H. S. & CO. having purchased from the Trustee the Stock-in-Trade of Mr. J. Methersill, of 6, Southampton Row, and 60, Holloway Road, London, at a large reduction off cost price, are offering it at a little more than half ordinary prices. Send for List, post free on application.

# THE WORLD OF ROMANCE.

WITH NEW AND ORIGINAL ILLUSTRATIONS.

***PART 1 ready SEPT. 24, price 7d., including LARGE PRESENTATION PLATE.***

"THE WORLD OF ROMANCE" will form a representative collection from the romance of all ages and all countries. Its pages will be filled with the strangest company, and will tell of the exploits and adventures of gods and heroes; of giants and fairies; of mermaids, hydras, and chimæras dire; of ghosts and vampires; stories of knight errantry and chivalry will take their place with tales of the monkish chronicles; the modern masters of romance will be found side by side with the Arabian chroniclers. There will be stories of fear and stories of gallantry; stories to chill the blood and to make it run briskly in the veins. The book will be even more fascinating than "THE WORLD OF ADVENTURE," and will have the same Editor as that most popular work.

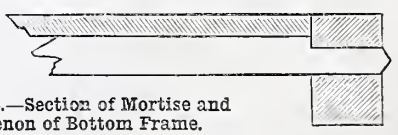

Fig. 6.—Section of Mortise and Tenon of Bottom Frame.

HOW TO MAKE A "TIP" CART.

## HOW TO MAKE A "TIP" CART.

BY J. P. S.

VARIOUS NAMES FOR THE "TIP" CART—MATERIALS—QUALITY—BOTTOM FRAME—FRONT BAR — IRONWORK — SHAFTS — BODY — BOTTOM — FRONT — TAILBOARD — BLOCKS — GENERAL HINTS—PAINT.

I CAN well understand many readers of WORK asking, "Who cares to know about that?" My reply to such must be, "A canny Scot." The readers of this journal are a host, and their wants are very varied; not a few of them are anxious to be instructed in making carts and vehicles of many descriptions, and amongst the number is this Scotchman; and as our Editor turns no one empty away, and the space allowable in "Shop" would be inadequate to treat such a subject fully, I am granted leave to put it in a special article as now set before you.

I have given what is known in my neighbourhood, where Scotchmen are fairly numerous, as a "Glasgow" pattern cart. It is fitted so as to empty its load very expeditiously. In "the land o' cakes" it is called a "coupe" cart; in East Anglia similar carts are designated as "tumbrils," but the more general name in trade circulars is "tip" cart.

*Materials.*—Our first thoughts must be given to materials, and while we are about it we may as well get the whole of the hard wood at one investment; consequently, we will prepare a list to take to the timber merchant. We shall require:—

| | *Marked.* | *Length.* | *Depth.* | *Thickness.* |
|---|---|---|---|---|
| | | ft. in. | in. | in. |
| For sides, 2 pieces of oak | A | 6 0 | 5½ | 3 (tapered) |
| For bars, 4 pieces of oak | B | 3 8 | 1½ | 3¾ |
| For front bar, 1 piece of oak | C | 4 8 | 2¼ | 3½ |
| For standards, 8 pieces of oak . . . . | D | 2 0 | 1¾ | 2¾ |
| For raves, 2 pieces of ash | E | 6 2 | 1¾ | 2½ |
| For front shaft bar, 1 piece of ash . . . | F | 3 3 | 3¼ | 3¾ |
| For hind shaft bar, 1 piece of ash . . . | G | 3 3 | 2 | 3½ |
| For shafts, 2 pieces of ash | H | 9 0 | 3¾ | (tapered) |
| For tailboard (top), 1 piece of ash . . . | J | 5 0 | 3¾ | 1½ |
| For tailboard (bottom), 1 piece of ash . | K | 4 9 | 3¾ | 1½ |
| For tailboard (centre), 1 piece of ash . | L | 4 9 | 1½ | 1½ |
| For front top rave, 1 piece of ash . . | M | 5 0 | 1½ | 5 |
| For cant piece, 1 piece of ash | N | 3 8 | 3½ | 2 |

Also 2 blocks, and a quantity of boarding 1 in. and also ¾ in. thick. The shafts and top rave of the front of body being crooked, templates will be required to saw them out by. These templates should be made of wood at least ⅜ in. in thickness. All the sizes given are "finished" sizes, and the lengths are longer than shown in the drawings, for reasons that will explain themselves as we proceed.

*Quality.*—The oak must be straight-grained, and free from *large* knots, at all events, and by no means use a piece that contains a bunch of "pin" knots. Timber so embellished looks ornamental while growing, and may answer for building or cabinet-making purposes, where it is not liable to varying loads and sudden strains, but it is wholly unsuitable for cart-building. Nor should the trees be too large or old, as oak loses much of its toughness with age, although—especially when well seasoned—it is often very hard and rigid. For cart-building purposes I prefer oak trees not exceeding 14 or 15 inches in diameter. The remarks as to straightness of grain and freedom from knots refer with equal force to the ash we may require; the shafts especially must be very tough. Much ash is spoilt by being felled after the sap has commenced to rise; it is invariably more or less soft if felled after February 1st, or if steam-dried instead of by the old and slow, but superior, methods used by our grandfathers.

*Bottom Frame.*—We must commence to erect by planing up the two largest pieces of oak, marked A, and the four pieces for bottom bars, marked B in Fig. 1. The hind edge of the hind bar must be perfectly straight; the other edges of all the others may be planed off to make the bars taper slightly in their width. This will allow our framing to drive together tighter, as well as increasing the strength of the bars in the centre. When the six pieces are true, straight and square, we will proceed to lay them out. We first lay our two pieces of oak side by side on a pair of stools, and proceed to measure off the distances, first of the hind pommels and also of the four bars, putting a short pencil-mark to denote the place of each. Our next proceeding is to consider—Are we going to use an axle which is to be made to order? If so, we can work to the drawing. Or have we bought a new one already finished from the ironmonger? Because in that case we must frame our cart such a width so that the pin-holes for the axle will come in the centre of our oak side pieces. The same holds good if we are using a good second-hand axle. Having settled this important point, we proceed to lay out the frame, bearing in mind *not* to lay the two side pieces parallel, but to make it 1 in. wider behind than in front. This is important, as I once saw a load of wet sand refuse to leave when the cart was "tipped," and consequently a shovel had to be used to unload it. As our cart is narrower in front than behind and our bars are taper, and, moreover, our mortises and tenons must fit very tight, I need scarcely say it is impossible to mark them off with a square and pencil as a joiner would soft wood framing; but instead, the framework must be laid out on the stools, squared with a rod, and the mortises scratched with a pointed piece of steel (a disabled gimlet ground to a point is what we use) in lieu of a lead-pencil. The tenons of the four bottom bars are "fair-faced" from the bottom side, and the shoulder is on the top. This is so done for strength. A tenon and mortise is given in section at Fig. 6. We invariably smooth up such work and drive it together at one operation, but it will be safer for a novice to drive it together in the rough and see that it comes accurate, and knock it to pieces again. Smooth up the bottom bars, and take a chamfer off the bottom edges; round off the rear ends of the sides to form the pommels, and then proceed to drive it together again for the last time, and pin it with oak pins. The ends of the pommels are finished by an iron band being driven on each.

*The Front Bar.*—We must next take the front bar, C, in hand. It is allowed to project 5½ in. each end to form handles. You will observe the ends are only 2¾ in. square, yet between the two oak sides of the frame it is 3¾ in. wide; the extra width has to be rebated out 1 in. deep to form a support for the front ends of the bottom boards; if the bar was carried through its whole width, it would not only unduly weaken the front end of the sides, but would also look very clumsy. The front bar will require fitting down in its place very exact; and here comes in a reason for our two oak sides being longer than necessary, as, if they were of the exact length, we certainly should break off the two "knucks" were we to drive the front bar into its place as tight as it should be. Perhaps someone will inquire the limits of the tightness allowable. My old master used to carry a piece of broken watch-spring in his waistcoat pocket, and woe betide us if he could insert it into our joints or mortises!

*Ironwork.*—Having done so much, we can go but little further without the aid of the smith. We shall want eight standard bolts, as at Fig. 9, and two front corner standards, as at Fig. 10. The iron bar across the rear of the body, with its bolts and two mortise holes for the tailboard, may be fitted at this stage, and it will be highly convenient to get the "tipping" bar, the jaws (Fig. 11) that hold it and its spring, and mortise plates at the same time, as they can be fixed in position far more readily now than at a later stage. If we are waiting for the smith, we may get out our eight wood standards, D, which are shown at Fig. 7, but we must not cut the top tenons until the standards are bolted into position and the raves have been marked on. If we are still waiting, we may proceed with the shafts, H.

*The Shafts.*—The drawings will make these fairly simple, I think. One is given showing the top side and the other shows the bottom; and to prevent any chance of an error, as the materials are costly, I have given an elevation, cutting away the bars to economise room. The hind bar, G, is not so strong as the front, F. The mortises are clearly shown, as is also the ironwork. The front bar has a plate of coach hooping the whole length of its top side, fastened down with wood screws, except the two end holes, which are countersunk for rivets. The underside has two T-plates of iron fastened with four rivets each, as well as wood screws. Each shaft has a band of hooping on its rear end, and the holes for the long pin are protected by plates of iron, as shown. The drawing shows a draught-hook on the slide staple, and also an eye further back; both are not necessary, consequently you are free to choose which you may prefer. The eye gives a steadier draught, in the estimation of many. The shafts being finished, they may be hung, and the irons and bar fixed for "tipping." Both catches are shown in elevation on the same shaft (Fig. 2), but it will be understood that one goes in the near and the other in the off shaft; the drawing is to show their relative *positions*. Having hung the shafts and fixed the "tipping" irons, we may withdraw the long bolt and set the shafts away while we proceed with the body.

*The Body.*—If the two iron standards are ready, fix them first, and be certain that they are not only the right bevel, both forwards and outwards, but also that they are both fixed alike. The wood standards, D, must next be bevelled to stand at their correct angles, and it will be as well to fit and fix them all in pairs, commencing with the two hindermost, which you will observe are slightly wider than the others. The standards are set out at irregular distances to admit of the bolts escaping contact with the

bottom bars. Be careful not to batter the heads of the standard bolts, or you will disgust your smith, who usually takes pride in finishing them well. When the standards are bolted up tight, the raves may be marked on and mortised, and the tenons cut on the standards. Next fit on the front top bent rave, M (Figs. 3, 4); and when this is done, shave the raves and standards, fix the tailboard irons (Fig. 14) on the rear ends of the raves, and fasten all together very firmly, seeing all is accurate as you proceed step by step.

*Bottom.*—This had better be next boarded; use good yellow deal or tough elm boarding 1 in. thick. It will lay in the rebate in the front bar, and it will require rebating behind to allow the hind iron bar to lay flush with the top of the boarding. The thin end of the bottom boards is shown in section at Fig. 5. The bottom being securely fixed, and the hind bar also, the sides will be ready for boarding. These boards should also be of good yellow deal or pitch pine, although I have known good Scotch fir to be used with success. The front ends give an opportunity for ornamentation, and the rear ends are protected by a fillet, A, being nailed on the outsides behind the standards. This brings us to the fore ends.

*Front.*—The cant piece, N, must first be fitted, made the correct bevel, and fixed with strong spikes. Next fit in the outside boards, which must be treated very carefully, or the wood may be spoiled. When fitted, it may be ornamented by cutting out and chamfering as shown in Fig. 4. If preferred, the board may be allowed to remain solid and the effect produced in paint; but for myself, I prefer to cut it out. The inside boards are fixed with the grain running from the top to the bottom, and the lines indicate where the joints may come. All the boarding except the bottom is $\frac{3}{4}$ in. thick. To prevent any errors in this front I have given a drawing in section, at Fig. 8, of the cant piece, top rave, and boarding.

*Tailboard.*—This is not double-boarded, or it would be too heavy. The two nib-irons (Fig. 12) on the bottom rail, and the two diamond plates with the pin-holes, are fixed with rivets, or they would soon jar loose. The $1\frac{1}{2}$ in. square strip in the centre is to bind the boarding and make it more rigid.

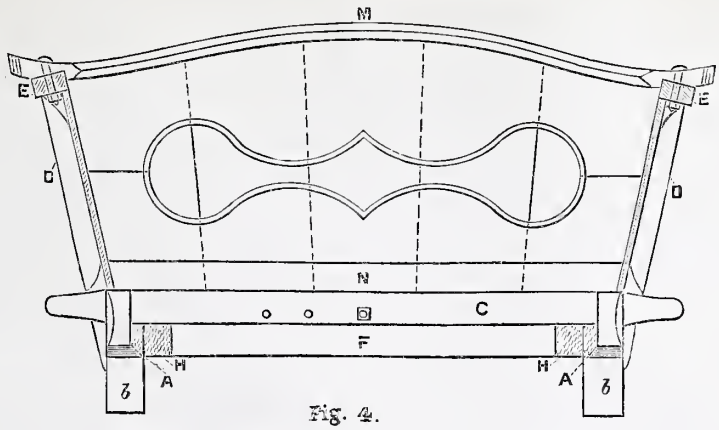

Fig. 4.

**Fig. 4.—Front of Body of "Tip" Cart: Elevation.**

The keys are fixed to the tailboard with small chains and staples, and in my drawing at Fig. 5 the tailboard is cut away to show the square line that gives the bevel of the cart.

*Blocks.*—These remain to be fixed, and the holes bored for the long axle-pins (Fig. 13). Two iron plates may be spiked to the blocks, *b*, to keep grit from working into the rear of the axle. The arms of the axle are $2\frac{1}{2}$ in. in diameter. The wheels are 4 ft. 4 in. high and the tires 4 in. wide. To a "Southerner" the front rave bands are very hideous, but they are the joy of the soul of a Scotch smith.

*General Hints.*—Much more instruction may often be given in the same space by drawings than by words; consequently, I fear I have given what may be considered an excess of drawings. I trust they may tell their own tale. I have endeavoured to help a young farmer, say, who has not had a training, and wishes to make a cart without spoiling his materials. Again, the strength of all vehicles largely depends on a judicious blending of wood and iron; bearing this in mind, I have given shore stays and bottom stays at the hind corners. I may remark loose top-boards are sometimes added, 7 in. deep, all round the body. If desirable, they may form the subject for a future paper. I may add another word which is highly important. It is this: all the mortises and tenons should be put together, and all the ironwork painted, where it comes in contact with wood, with white lead, made into a smooth soft paste by the addition of equal parts of raw oil and turps. The pins holding all the mortises down on the tenons should be made of tough oak, and driven in with the white-lead lubricant. In no case can wedges be allowed; they are certain to shake out.

*Paint.*—The wheels, bottom and inside of body, the shafts, and also the ornamental space in front, are all finished red. For the remainder green is the favourite colour. The ironwork is finished a deep *blue-black*, and so forms a relief and looks well.

If readers wish to know anything which may not be quite clear, inquire through "Shop"; it is always open, and I am yours to command.

## ENGINE AND BOILER MANAGEMENT.

BY M. POWIS BALE, M.INST.M.E., A.M.INST.C.E.,

*Author of "A Handbook for Steam Users," "Wood-working Machinery," "Stone-working Machinery," "Pumps and Pumping," etc.*

### ENGINES.

POUNDING OR KNOCKING OF ENGINES—ENGINE CYLINDERS CRACKING—QUICK METHODS OF SETTING A SLIDE-VALVE—HOT BEARINGS—HOT CRANK PIN BEARINGS.

I NOW bring to a conclusion my remarks on this important subject. For preceding papers the reader is referred to pages 229, 290, and 354.

40. *Pounding or Knocking of Engines.*—Pounding or knocking may arise from a variety of causes. If the knocking is at the end of the stroke when the crank is on the "dead centre," it may arise from wear on the connecting-rod bearings, or from their not being keyed up tight enough, or from the piston-rings being broken too loose at the guide-bar end, or from a ridge or inequalities in the cylinder or guide-bars. Knocking, when the crank is at half-stroke, will not be caused by any of the above reasons except the piston or piston-rings being loose, which

would cause a knocking sound as the crank came over the dead centre and at the end of each stroke. Knocking or clicking of piston-rings may also be caused through water being in the cylinder, either from the boiler priming or from condensation of steam. It may also arise from the engine-shaft, cross-head, or slides being out of line, or from insufficient cushioning of the piston, or from a slack nut at the end of the slide-valve rod, or valve rod bent from an accumulation of dirt. Knocking may also be caused from the axes of all the journals not being parallel.

41. *Engine Cylinders Cracking.*—There is little doubt that the "mysterious" cracking of engine cylinders which occasionally occurs arises in many cases from the want of ordinary precautions on the part of the driver. Drivers often get up steam and start their engines as soon as possible, and the steam is let into the cylinder when it is cold, consequently an immense strain from sudden and unequal expansion is set up. It is, therefore, advisable, especially with large engines—more particularly in frosty weather or exposed situations—that the cylinder be thoroughly warmed before starting. There are, of course, other reasons for cylinders cracking: such as the use of improper or unsound metal in their construction, improper proportion of metal, water or ice in the cylinder, broken piston, engine running away, etc. The cylinder, if steam-jacketed or not, should in all cases be carefully covered with a good non-conducting material to prevent radiation of heat.

42. *Quick Methods of Setting a Slide-Valve.*—(1) Make the eccentric-rod of such a length as will permit the valve to open equally at both ends of the stroke. Then put the crank on the dead centre, and turn the eccentric round the same way as the engine is intended to go, altering until the valve moves through a distance sufficient to give the required lead, and you may rely on its being the same on the opposite side. (2) Another plan (Dunn). Remove lid from steam-chest, revolve the main shaft or slack the set screws in eccentric, and revolve eccentric until full throw of same is made in one direction, opening the port to its largest size. Now make a tapered wedge out of a lath and slip it down in open port, marking with a knife or pencil the edge of wedge on valve-seat. Now revolve eccentric until full throw is made towards opposite end of steam-chest, and until port is open to its largest size; then slip the wedge down in port as before; then with a rule divide the distance between the two lines on edge of wedge, marking a third line in the centre; then, with the eccentric at full throw, lengthen or shorten the cam-rod until the wedge, with its centre line, fits one port neatly, and it will fit the other one as neatly when full throw is made in the opposite direction. Now place your engine on a centre, and revolve eccentric until the port over the end of cylinder, in which the follower is placed, has opened about $\frac{1}{16}$ in., and tighten your set screws. This done, your slide-valve, also your eccentric, is properly adjusted, and no time wasted in hunting dead-centre or chalk-marking fly-wheels.

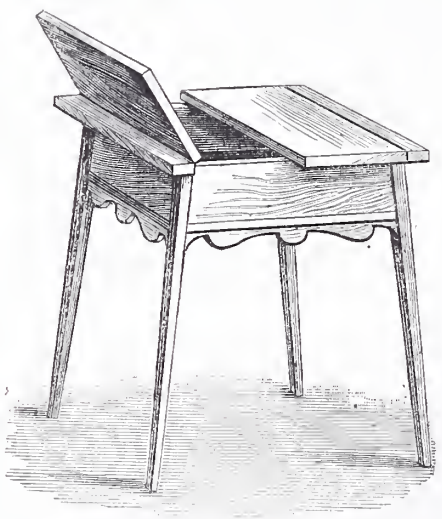
43. *Hot Bearings.*—Heated bearings may arise from a variety of causes: such as (1) Bearings of insufficient area for the pressure or strain put on them; (2) engine running at short centres with a tight belt; (3) bad-fitting or seamy shaft; (4) bearings screwed up too tight; (5) insufficient lubrication, improper or bad oil; (6) dust or dirt in the bearings, oil-grooves too shallow, or oil-ways stopped; (7) bearings will also stretch and pinch the shaft from being allowed to run slack or get out of line or level; (8) from oil-boxes or lubricators being or becoming air-tight, and preventing the proper flow of the oil; (9) from the axes of all the journals not being parallel, or from the shaft not bedding evenly on the bottom of the bearings.

44. *Hot Crank-Pin Bearings.*—More particularly with engines in which the connecting-rod is arranged to work on to a crank-pin, considerable trouble is often experienced through the bearings heating. This may arise from their being poorly fitted, from requiring adjustment, from want of proper lubrication, or from the bearings being made too thin, sufficient metal not being provided to carry off the heat engendered from working when the bearing was slightly out of order. Apparently well-fitted bearings may heat from another cause, and one that has puzzled a good many in detecting, and that is from the connecting-rod being out of line. To detect this, take the connecting-rod out of the cross-head and key it up tightly on the crank-pin. Now move the rod up and down, and see that it drops truly into the bearing on the cross-head; if it does not, you will know it is out of line, and should be overhauled and adjusted at once, as the bearing will never run cool under these conditions, it being very much strained, and the area in contact with the crank-pin being largely reduced. If, on examination, you find the bearings are wearing bell-mouthed, you may conclude it arises from the last-mentioned cause. A similar trouble may arise with engines in which a sweep-crank is used, but it is not so pronounced.

## A BOX-TOP TABLE.

BY JAMES SCOTT.

During a stroll lately among the London streets, the shops in which teem with high-class furniture of every description, my attention was directed to a table similar



A Box-Top Table.

in appearance to the one represented here. Of the utility of it no one should possess one particle of doubt, for it must be apparent in plain boldness that an article of this kind can be used as a storehouse for odd-ments and small knick-knacks which may be deemed indispensable, although troublesome by reason of their smallness. Again, with both wings or flaps opened, allowed to rest horizontally, the under surfaces of them being uppermost, the article could be used as a tea-table, the area of the flaps, when opened, being almost as large as when closed over the box; while, in addition, the cavity would be found suitable for the reception of tea-pot, bread-tray, sugar-basin, etc. Indeed, it might be considered a very advantageous matter to adapt the table solely to purposes of this kind, and, constructing the article in such a way that the capacity of the box portion is sufficient, store all accommodating adjuncts to a tea-meal within the interior when not required for use. Of course, it would be a source of inconvenience to use a cloth with which to cover the table, as occasion might frequently arise for application to the box; but a well-polished or prettily enamelled piece of furniture has no need of being hidden under any sort of cloth.

It may be noticed that there is so little extra labour necessary to construct the table as a box article than would be required to make it in the ordinary way, that it ought not to call forth any objections in this direction; while it must be admitted that the box answers all the facilities of a drawer without necessitating the extra work of making one.

The reader is requested to note that the narrow end top pieces, to which are attached the flaps that form the table-top, must be fastened to the framework of the table.

Some readers may remember (or if they will refer they will see) that I gave a similar suggestion to that contained in this table in reply to a correspondent in page 653, Supplement, No. 92, Vol. II. (issue for December 20, 1890), in the upper portion of a tool-chest. Whether the present article is adapted from my idea in that number I cannot positively say, for it is impossible to keep pace with all fresh improvements; but certainly I can say that on my part originality, and not copying, was foremost. The flaps, as an alternative, could be hinged as shown in the number of Work quoted.

## BOOT AND SHOE REPAIRING.

BY W. GREENFIELD.

### Half-Heeling—A Novel Way to Keep the Heels Level.

In this article of our series I want to impress upon my readers the great importance of keeping heels level, for if they are allowed to wear down low, the ill that is caused by it is difficult to remedy. For it not only tends to throw the heel itself on one side, but it causes the sole to wear away much quicker, runs the stiffener down at G G (Fig. 1), and generally throws the boot or shoe out of position beyond recovery.

Nearly everybody in walking wears down the heels of their boots at one particular spot. This should be most at A (Fig. 1), though with some it happens right at the back of the heel, while a few wear most on the inside. Now, to repair these defects is nearly one of the best jobs that a novice can start upon, inasmuch as the grafting in half-heeling only means butting the new piece of leather against the old, as there is no play or friction to cause them to come asunder. In the boots and shoes that are manufactured now so very cheaply the leather is not what is called "properly worked"—that is, as I have previously mentioned, "wetted, dried, hammered," etc.). This causes what I daresay most of you have experienced—namely, a

new pair of boots worn out in the wet are, when taken off the feet, lower on one side of the heel than the other, although the leather is not actually worn away. This is because it yields to the pressure and weight of the body in walking, and the yielding is their first step to ruin.

To prevent this, when you buy new boots always ask them to put a few extra nails just round the part where you know you wear most. When the heel is only worn down on one side it is not necessary to take the whole of the top piece off, but only half of it, which can be replaced with any hard corner of sole leather that would otherwise be almost useless.

To do this, saw the top piece across at B C, and should the lift be worn, saw or cut that through as well at D E; tack a piece of leather on to take the place of the worn piece of lift, putting the tacks in at F and F. Then trim it round, and put some odd hard corner of sole leather on in a like manner, to take the place of the worn part of the top piece. Trim this up also, and nail as shown in Fig. 2. In this case you will need to put four of the rivets in, quite ¾ in. long, at A, B, C, and D, so as to hold the lift as well as the top piece. Of course, you can put one, two, three, or four rows, as you please, but they are not much use unless they are close together; and two rivets should be put in, one on each side, as shown at E, F, G, and H. This done, file them up, and finish in the ordinary way.

Now, as I have said above, it is all important to keep the heels level. You will not be surprised, I hope, that I have tried to gain or obtain this desideratum with the idea (simple as it may appear) that it is of great importance to those who mend and study their own boots.

Certainly, half-heeling, with plenty of nails close together, and regularly done, will keep them in proper order; but everyone cannot always spare their boots or spare the time to do them properly in this way, and it is a job that, once started, the boots cannot be worn again until they are finished. Hence the need of a method that is either quicker or that can, in some way or other, be more divided.

Now, the best thing is never to wear a top piece quite through, for you touch the lift if you do; and, no matter how little this may be, it will need either replacing as described above, or repairing by means of a skiver put under.

But, prior to letting them wear away, take a piece of paper with one straight side and lay this across the heel, from J to H, Fig. 2; hold it with two fingers of the left hand quite firm at F and G; then with the right hand smooth it down over the edge from J, passing A, B, C, and D on to I. This will leave a mark on the paper; cut it out to this mark, and it will give you a good pattern of a half-heel piece, as Fig. 3, without the outside line A. To this you can cut another pattern out of stiff cardboard, as you will want to use it very often.

This done, and you have any more leisure, cut a piece of sole leather out to this pattern, leaving ¼ in. on all round the curved side A, Fig. 3—this to give room for nailing. But before I show how this should be done it will be necessary to explain how to make a certain awl for this purpose. They cannot be bought, like all other awls, ready for use, but as it is a tool that saves much time and disappointment, I will describe how it can be made, and also a suitable handle for it.

Now, to make this tool you want, first of all, an ordinary peg-awl handle, as A, Fig. 4, and put two pieces of sole leather on top, as B and C. To secure these, put one short stout screw in the centre, and then put a third piece on, as D, first cutting a hole in the centre, a little larger than the head of the screw, as A, Fig. 5, and then put about five rivets in, as B, C, D, E, and F. This is done because the awl, when finished, is very stumpy, and requires such hard blows to get it in that it would split the wood, and by this means you throw all force on the leather, and the hole in the centre will admit of tightening the screw when necessary. This done, and the edge trimmed up all round, put into the other end a carpenter's large bradawl. This kind of awl, as most people know, has a square shoulder to it, therefore the heavy blows will not drive it up into the handle. When the awl has been put into the handle, break it off to about an inch of the shoulder; then with a fine file, or on a grindstone, if you have one, taper it to a long, flat, square point, as E, Fig. 4; in fact, it should be just the size and shape of a French brad, only about ⅛ in. longer, and, of course, smooth.

The piece of leather in Fig. 3 should be of good substance, and should be wet, but not soddened; then mark a line round the curved side from B to C, ¼ in. from the edge, and from these two points make two rows of holes with the new awl, which should, by the way, be dipped each time before using into a piece of soap. A hole can be missed in the second line of holes at each of the four places D, D, D, D, and a small round hole made instead; and four more also made at E, E, E, E, and then let the leather get nearly dry, that you may hammer it as before explained.

This will make the holes smaller and look more irregular, as shown in Fig. 3; but that does not matter so long as the awl was held in the same position for each hole, for the brads are sure to follow into their proper place.

I said above that the awl should be of the same shape as a French brad, which is as B in Fig. 6; but there is another kind of brad the same shape, only it is much shorter and a little stouter, as A in Fig. 6. These are called cut-bills, and it is this brad you must use to put into the holes made in Fig. 3. Let the length be as near the substance of the leather as possible, knock them in the square holes one at a time, and when they are all in take the leather off the wood (the best thing to do the bradding on), and lay it on the lap-iron with the points of the brads upwards. These, if they are not too far through, can be clenched and made smooth by tapping down with a hammer, but if they are through far they must be cut off with a pair of cutting tongs close to the leather before trying to clench them.

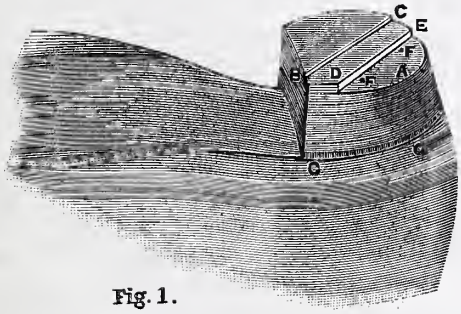


Fig. 1.

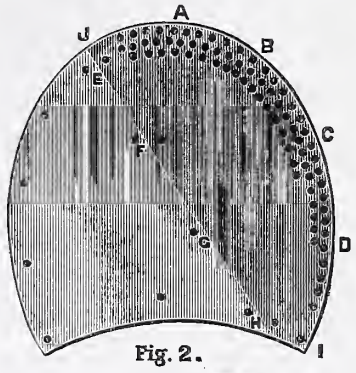

Fig. 2.

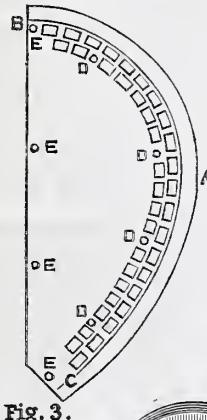

Fig. 3.

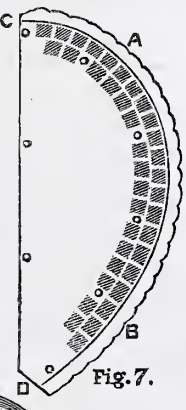

Fig. 7.

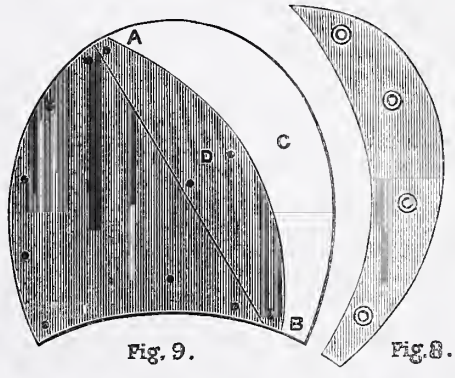

Fig. 9.

Fig. 8.

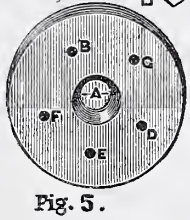

Fig. 5.

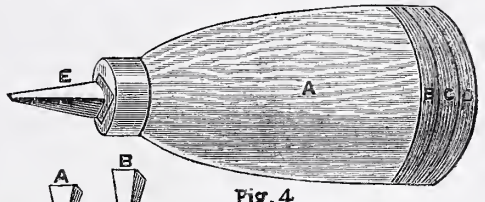

Fig. 4.

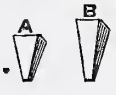

Fig. 6.

**Fig. 1.—Heel with Worn Part of Lift and Top Piece cut away to receive Piece Lift and Half-Heel. Fig. 2.—Top Piece levelled by Half-Heeling, with three Rows of Rivets close together to resist wear. Fig. 3.—Half-Heel Piece holed and hammered. Fig. 4.—Home-made Awl and Handle. Fig. 5.—Top of Awl Handle with Hole through Centre. Fig. 6.—A, Cut-bill; B, French Brad. Fig. 7.—Half-Heel Piece bradded, ready for future use. Fig. 8.—Snow's Patent Leather-Plugged Half-Tip. Fig. 9.—Top of Heel, showing how to fit for Half-Tip.**

This done, they are ready for use, and you can keep as many prepared as you wish, and all that is necessary then to half-heel the boots is to cut the top piece across, as shown, from J to H, Fig. 2, take the worn part away, and replace it with the new piece (Fig. 7), which shows the way it should be bradded, and also the eight places for a like number of ⅝ in. rivets, which is all that is necessary to hold it on, and will let it be taken off easily when another piece is wanted on.

It will be found that the small margin, A B, Fig. 7, after the brads have been put in, has become somewhat contracted. This is why the extra ¼ in. is left on, for if nailed close to the edge the leather would break out, whereas now you can trim up the edge of the piece to the edge of the heel, cutting right close to the brads, as the line C to D, and finish in the ordinary way.

It will be necessary to put four rivets in the old leather at E, F, G, and H, Fig. 2, the first time they are half-heeled, to keep it from ripping off.

Another good and easy way is to get a pair of Snow's patent leather-plugged half-tips (Fig. 8), price 1½d. Put it on the heel in its proper position, and mark round the inside from A to B, Fig. 9, and cut that part away that the tip is going to replace, as C. Lay the tip on the lap-iron face down, and tap it in the centre, that it may grip well at both ends, then just dip it in water to soften the leather plugs, and put it on the heel; with a fine awl make a hole through the centre of each plug, and put a long rivet (which they should give with the tips) in each hole; file it up anywhere where rough, and you have a new lease of heel wear for 1½d., and a very little trouble.

Should you find it difficult to cut the curved line to fit the tip from A and B, cut it straight across, as you did in Fig. 2, from J to H, and after the tip is on cut a small piece, as D, Fig, 9, and nail it in with four rivets.

To get D the proper shape, let it have one straight side, press that against the old leather, and hammer the new on the tip. This will make a mark underneath: cut through this line, and you have the shape required.

## FRENCH POLISHING—"DRY-SHINING."

BY DAVID DENNING.

EMPLOYMENT—METHOD OF WORKING.

THE ordinary methods of French polishing having been fully described, the novice who has managed to do "bodying up" and "spiriting off," or even "glazing," will find the operation of "dry-shining," which is the subject of the present article, mere child's play in comparison.
